LIBRARY
OF THE
BIBLIOTHECA
MUSEI
HISTORICO-NATURALIS
ROMAE

INDEX TO VOLUME I., 1923.

Readers in search of a given subject will find it useful to bear in mind that the references are in several cases distributed under two or more separate but nearly synonymous headings—such, for instance, as Brain and Cerebral, Heart and Cardiac, Liver and Hepatic, Child and Infant, Goitre and Thyroid, Diabetes, Glycosuria and Sugar, Eye, Ophthalmic, and Vision, Lunacy and Mental Disease, Arsenobenzol and Salvarsan, &c., &c. (Py Q)=Parliamentary Question.

A Concordance of page numbers and dates of Issue will be found at the end of the Index.

A

- Aarons, Dr. J., death of, 875
 Abdomen, acute, in the child, 81
 Abdominal emergencies, undiagnosed (leading article), 291; injuries, treatment (Prof. C. A. Morton), 298; operations, after-treatment, 1059
 Aberdeen Medico-Chirurgical Society, Records, 1789-1922 (Mr. J. S. Riddell) (review), 136
 Aberdeen Medico-Chirurgical Society (see Medical Societies)
 Aberdeen Royal Infirmary, report, 441; resignation of Sir H. Gray, 932; Royal Asylum, report, 464; Dispensary and Vaccine Institution, report, 727
 Aberdeen University, Gala Week, 1080
 Aberdonians, distinguished, 710
 Abortion, should it be induced for tuberculosis? 556; suppression of, in France, 1076
 Abrahams, Mr. R. G., suprarenal tumour with metastases in skull, 386
 Abrahamson, Dr. L., paroxysmal tachycardia, 132
 Abscess, Brain (Dr. W. P. Eagleton) (review), 1062
 Abscess, liver, treatment by aspiration (Dr. P. Manson-Bahr and others), 941, 1026; cerebral (Dr. J. P. Parkinson and Mr. L. R. Broster), 1107; lymphangitic, suppurative thyroiditis or, 1222
 Accidents, serious, in shipbuilding yards (Py Q), 828
 Achlorhydria and pernicious anaemia (Dr. A. F. Hurst), 111
 Acid-base equilibrium of the blood, 348; of body-fluids, revised nomenclature, 613
 Adami, Prof. J. G., "Charles White, of Manchester, and the arrest of puerperal fever," 395; pathology of influenza, 665
 Adams, Dr. W. B., ulcer epidemicum, 1071
 Adams, Mr. A. W., gluteal aneurysm and rupture treated by Antyllus's operation, 697
 Adams, Mr. J. E., education in cancer problems, 404, 597
 Addison's anaemia (Mr. H. Gilford), 64
 Adenitis, cervical, unhealthy tonsils associated with (Dr. W. G. Howarth and Dr. S. R. Gloyne), 1202
 Adolescents and drunkenness (Py Q), 516
 Adrenal insufficiency in experimental animals, 556
 Adrenalin "ciba," 1320
 Adrenalin, intracranial injection of (Dr. C. Bodon), 586
 Advertisement, indirect, 346
 Advertisements on official forms (Py Q), 1085, 1246, 1293
 Aerocoele, traumatic intracranial (Sir W. Wheeler), 529
 Agricultural workers and health insurance (Py Q), 1193
 Albino, a Sudanese (Dr. H. E. S. Stiven), 648
 Aleptonuria, heredity in (Mr. C. F. Cuthbert), 593
 Alcohol and insanity (leading article), 239, 405, 509, 619, 722, 769, 821; and age limitation, 500; and pneumonia, 967
 Alcoholism, international congress against (Py Q), 1246
 Alexander, Dr. D. A., infective endocarditis in the elderly, 160
 Alienists, attacks on, by the insane, 1275
 Allbutt, Sir T. C., composition and style, 811; angina pectoris, 883; the pain of pseudo-angina, 1025; cause of death in angina pectoris, 1131
 Allenbury's diabetic flour, 30
 Allingham, Dr. W., death certificates and the coroner, 406
 "Almata," 30, 342
 Alt, Prof. F., death of, 202
 Amaas and small-pox, 101, 564; in South Africa, 205
 "Ambulance," 1031; competition tests, 1142; facilities, 1343
 Ambulances, need for more, 810; licence duty on (Py Q), 829
 American relief work in the Near East, 46
 Ammon, Dr. S. E., and Dr. A. R. Mathe-son, effect of histamine on the human gastric secretion, 482
 Amoebiasis, emetine bismuthous iodide in, 157
 Amrein, Dr. O., Lungentuberkulose (review), 1269
 Anaemia, Addison's (Mr. H. Gilford), 64; pernicious, and achlorhydria (Dr. A. F. Hurst), 111; pernicious (Dr. P. N. Pantou and others), 275; pernicious, vaccine treatment in, 406, 457; pernicious, oral sepsis in relation to, 458
 Anaesthesia, ether, 36; spinal, 196; and cardiac-vascular conditions, 284; sugar, and alkalies, 298; in ordinary dental practice, 487; nitrous oxide, death following, 664; for removal of tonsils, 860
 Anaesthesia in Children (Dr. C. L. Hower) (review), 82; Regional (Dr. G. Labat) (review), 902
 Anaesthesia, splanchnic (leading article), 962
 Anaesthetic action of pure ether (Dr. H. H. Dale and others), 424; new general, 619; gas, new, 719
 Anaesthetics, deaths under (leading article), 910
 Anaesthetics, Practical (Dr. C. F. Hadfield) (review), 82
 Analytical Records (see Reports and Analytical Records)
 Anaphylactic shock (Dr. J. Fawcett and Dr. J. A. Ryle), 325
 Anaphylaxis and immunity, 245; and the administration of serum, 924
 Anatomical terminology (British or Continental?), 212
 Anatomy building, new, at University College, London (Prof. G. E. Smith), 865
 Anatomy, Cunningham's Text-Book of (Dr. A. Robinson), fifth edition, 1922 (review), 135; Practical (Dr. R. J. A. Berry), second edition, 1922 (review), 135; Surgical, Manual of (Mr. L. Beesly and Dr. T. B. Johnston), second edition, 1922 (review), 136; (Dr. F. Kiss) (review), 136; Dental (Sir C. Tomes), eighth edition, 1923 (review), 657; Practical (Prof. T. Walmsley) (review), 657
 Aneurysm, gluteal, and rupture treated by Antyllus's operation (Mr. A. W. Adams), 697
 "Angels," of the window-sill, 58
 Angina pectoris, surgical treatment of, 867; treatment (Sir C. Allbutt), 883; pseudo-angina, the pain of, 1025; cause of death in, 1083, 1131
 Angioma, cavernous, of the face 1112
 Aniline pencil in a bun, 110
 Animal Body, Oxidations and Reductions in, second edition, 1922 (review), 753; and its Environment (Dr. L. A. Borradaile) (review), 903; Parasites and Human Disease (Mr. A. C. Chandler) (review), 1163
 Animal diseases, study of, 297
 Animals, experimental, adrenal insufficiency in, 556
 Anrep, Dr. G. V., and Dr. T. D. Harris, Practical Physiology (review), 601
 Antenatal work and the late Dr. J. W. Ballantyne, 359; diagnosis, 398
 Anthrax, industrial (international labour conference), 142; infection by shaving brushes (Dr. R. A. Knott), 227; in East Indian wool (Py Q), 468
 Anti-antibodies, 812
 Antitoxin, diphtheria, delay in giving, 1189
 Antituberculosis legislation, proposed, in Germany, 817
 Antivivisection movement in Roumania, 46
 Antrum, the chronic (Dr. T. B. Jobson), 78
 Aorta, traumatic rupture of (Dr. P. R. Kemp), 953
 Apothecaries' Garden at Chelsea, 146
 Apothecaries Society of London, pass lists, 52, 209, 512, 725, 980, 1191
 Appeal tribunal cases (Py Q), 1028
 Appendicitis, 544; acute, 544; ascaris, 957
 Appendicitis and cancer, universality of, 50
 Appointments, weekly lists of, 54, 105, 161, 211, 261, 311, 363, 414, 470, 518, 574, 625, 677, 728, 774, 830, 878, 935, 984, 1033, 1087, 1138, 1196, 1247, 1296, 1346
 Approved societies' funds and medical benefit (Py Q), 984; administrative allowance of (Py Q), 1027
 Archer, Mr. H. E., and Dr. C. C. Twort, fatal nephritis, 1102
 Archibald, Dr. R. G., distribution of trypanosomes, 93; and Dr. W. Byam, Practice of Medicine in the Tropics (review), 803
 Armstrong-Jones, Sir R., puerperal insanity, 1297
 Army recruits in 1922, unfit (Py Q), 571; Medical Service, 624; medical service in (Py Q), 1029
 Arnd, Prof. Carl, obituary, 673
 Arnold and Sons, change of address, 110
 Arsenobenzol and the spirochete, 1223
 Arterio-sclerosis, nature of (Dr. G. Evans), 779
 Artery, mesenteric, thrombosis of (Dr. A. Cawadiaz), 949
 Arthritis, tuberculous (Dr. E. Ward), 11; chronic, glucose tolerance in (Dr. G. L. K. Pringle and Dr. S. Miller), 171; suppurative, simulating acute appendicitis (Mr. J. A. Berry), 486
 Asphyxia, traumatic (Mr. A. Moncrieff), 1307
 Ashby, Dr. H. T., diabetes mellitus in an infant, 22; croupous pneumonia in children, 702; and Dr. A. Sellers, chloroma, 1263
 Askey, Dr. S. G., opposition to panel practice, 407; streptococcal meningitis, 952
 Assam, health of the European community, 1249
 Assessments, conditional, reconsideration of (Py Q), 984; by re-survey boards (Py Q), 1086

537007

- Asthma cure, an alien, 158; in childhood (Dr. A. D. Fordyce), 175; peptone immunisation in (Dr. A. G. Auld), 790
 Asylum nursing in Paris, 760
 Atavistic degeneration and tuberculosis (Dr. W. C. Rivers), 120
 Athletic achievement, unique, 522
 Auden, Dr. G. A., congenital absence of the spleen, 101
 Auld, Dr. A. G., peptone immunisation in asthma, 790
 Aural discharge in children, treatment (Dr. H. Barwell), 351, 457
 Auricle, left, extreme dilatation of (Dr. J. G. Emanuel), 591
 Auricular fibrillation, treatment by quinine sulphate (Dr. J. G. Emanuel), 1050, 1072
 Australian Institute of Tropical Medicine, 347
 Austrian "Krankenkassen," present position, 670
 Auto-urine reaction, control for, 555
 Aveling's repositior, 545
 Aymard, Mr. J. L., Cure of the Deaf by Electro-Aeration (review), 491
- B**
- Bacot, the late Mr. A. W., memorial to, 679
B. diphtheriae, serological classification of, 184; fermentative reactions of, 436; *B. aertryke* infection (Dr. D. Firth and Dr. E. ff. Creed), 1212
 Bacteria, intestinal, influence of, upon the thyroid gland, 286
 Bacteria, Hemoglobinophilic (Martin Kristensen) (review), 189
 Bacteriology, primitive, 38; in ancient China, 101; diploma in, 1123
 Bacteriophage, the (F. d'Herelle) (review), 804
 Bacterium pneumosintes, 292, 408
 Balding, Dr. D., death of, 773
 Balfour, Dr. A., permanganate of potash in small-pox, 255; sojourners in the tropics, 1329
 Ballance, Sir C., Thomas Vicary lecture on the History of Surgery of the Brain (review), 29
 Ballantyne, Dr. J. W., obituary, 258
 Bandaging diagrams, 214
 Bankart, Mr. A. S. B., treatment of spastic paralysis, 537
 Bannerman, Dr. R. G., blood-plate counting in man, 1154
 Barber, Dr. H. W., treatment of scabies and pediculosis, 247
 Barcroft, Mr. J., apparatus for hydrocyanic fumigation, 1338
 Barium in the Harrogate waters (Mr. A. Woodmansey), 22; salts in mineral water, 39
 Barker, Dr. F., Endocrinology and Metabolism (review), 1010
 Barker, Mr. W. H., and Mr. L. Brooks, Junior Regional Geographies (review), 703
 Barling, Mr. S. G., and Dr. L. G. Parsons, pyloric stenosis of infants, 59, 207; chronic duodenal ileus, 235
 Barlow, Dr. N., and Dr. J. C. Thompson, spontaneous pneumothorax in pulmonary tuberculosis, 1276
 Barrett, Lady, women in the Post Office Medical Department, 567; prophylactic treatment of puerperal sepsis, 1279
 Bartholomew Fair, 938
 Barwell, Dr. H., treatment of aural discharge in children, 351
 Bastardy and Legitimacy Bills (leading article), 1271
 Basto, Dr. R. A., and Prof. C. Y. Wang, precipitation test for syphilis, 1262
 Bath Clinical Society (see Medical Societies)
 Baudoin, Prof. C., Studies in Psycho-Analysis (review), 134
 Baxter, Miss E. M., and Dr. A. J. Eagleton, serological classification of *B. diphtheriae*, 184
 Bayer "205," further experiences with, 393, 1026
 Bayliss, Sir W., The Colloidal State, in its Medical and Physiological Aspects (review), 339; use of saline solutions intravenously, 575; Vaso-Motor System (review), 655; Interfacial Forces and Phenomena in Physiology (review), 1162
 Beadles, Mr. H. S., deposit contributors to National Health Insurance, drawbacks of the system, 311
 Beadon, Dr. Mary O'B., enuresis treated by electricity, 283
 Beatson, Sir G., financial reconstruction of voluntary hospitals, 606
 Beckett, Henry Arnold, 811
 Bed isolation and infection (Dr. F. Thompson), 1146, 1158
 Bedson, Dr. S. P., anti-antibodies, 812
 Beesly, Mr. L., and Dr. T. B. Johnston, Manual of Surgical Anatomy, second edition, 1922 (review), 136
 Behnke, Miss K. E., treatment of stammering, 1083
 Belfast Royal Victoria Hospital, meeting, 674
 Bell, Dr. A. J., Feeding, Diet, and the General Care of Children (review), 547
 Bell, Dr. J. R., and Dr. A. F. Hurst, vaccine treatment in pernicious anaemia, 406
 Bell, Prof. B., intrinsic dysmenorrhoea, 845
 Benhamou, Dr. E., action of quinidine on goitre, 712
 Bennett, Dr. T. L., treatment of whooping-cough, 197
 Benson, Dr. W. T., detoxicated vaccines in diphtheria, 895
- BERLIN, CORRESPONDENCE FROM.—Medical fees; Medical study and examinations, 155—Organisation of the medical profession in Germany; Medical Courts of Honour, 156—Financial distress in Berlin hospitals, 400—German hospital system; Conscientious objection to vaccination, 401—Financial difficulties of Berlin Medical Society; Bill for combating venereal diseases, 561—Medical Minister of State; Meat poisoning in Freienwalde; Women students in Prussia, 562—Proposed anti-tuberculosis legislation; Temperance movement in Germany; Foreign patients in Germany, 817—Mercury poisoning, 818—Midwives Act; Proposed settlement of German medical men in Afghanistan, 1077—Cocainism in Germany; Public health in Prussia, 1078—Amendment of the Sick Club Act, 1282—Problem of decreased birth-rate; Organisation of the universities; Training of nurses for children, 1283
- Berry, Dr. H. P., death of, 30
 Berry, Dr. R. J. A., Practical Anatomy, second edition, 1922 (review), 135
 Berry, Mr. J., treatment of cancer of the tongue, 438
 Berry, Mr. J. A., suppurative arthritis simulating acute appendicitis, 486; coexisting uterine and ectopic gestations, 1157
 Bertwistle, Dr. A. P., silk-worm-gut holder, 164, 472
 Beyers, Dr. C. F., "subpleural" lipoma in a child, 283
 Bigland, Dr. A. D., diagnosis and treatment of migraine, 133
 Bile-ducts, hepatic and common, surgery of (Dr. W. J. Mayo), 1299
 Bilharziasis in Europe, 294
 Biochemistry, Laboratory Handbook of (Dr. P. C. Raimont) (review), 83; Fundamentals of, in Relation to Human Physiology (Mr. T. R. Parsons) (review), 703
 Biologist's continuum, 448
 Biology and Medicine, Greek (Dr. H. O. Taylor) (review), 657
 Birley, Dr. J. L., psychology of courage, 779
 Birmingham and Midland Skin and Urinary Hospital, report, 981; Pensioners' Hospital, fire at (Py Q), 1293, 1344
 Birmingham University, meeting, 361
 Birth-rate and national development in Austria, 455; in Germany, problem of decreased, 1283; French, diminution of, 1336
 Births, excess of, over deaths (Py Q), 1086
 Births, marriages, and deaths, weekly lists of, 55, 106, 162, 211, 262, 311, 363, 415, 470, 518, 575, 626, 678, 728, 775, 830, 879, 935, 985, 1033, 1087, 1138, 1196, 1248, 1296, 1346
 Bismuth as an antiluetic, 39; syphilis treated by (Dr. C. Levaditi), 639
 Blacker, Dr. G., treatment of menorrhagia by radium, 421; treatment of primary or spasmodic dysmenorrhoea, 814
 Bladder tumours, epithelial (Mr. F. Kidd), 523, 582, 636; (leading article), 706
 Bland-Sutton, Sir J., the affairs of John Hunter (1728-1783), 315; choroid plexuses and ventricles of the brain as a secreting organ, 1143
 Blarcom, Miss C. C. van, Obstetrical Nursing (review), 1114
 Blind, training centres for (Py Q), 516; local authorities and (Py Q), 517; schemes for (Py Q), 676; school-children (Py Q), 726; persons, workshops for (Py Q), 877
 Blind Persons Act (Py Q), 467
 Blinded soldier, treatment of, 44
 Blindness, war (leading article), 143; colour, 286
 Blizard, Mr. G. P., Dental Board lectures, 672
 Blood and cancer research, 146; acid-base equilibrium of, 348; pressure, high, reflections on (Sir H. Rolleston), 519; disorders of, and their ophthalmological manifestations, 953
 Blood-plate counting in man (Dr. R. G. Bannerman), 1154
 Blood-sugar (leading article), 707
 Blood, sugar in, estimation of (Dr. G. R. Lynch), 1178
 Blood-vessels, idiosyncrasies of, 915
 Board of Control, membership of (Py Q), 877; functions of (Py Q), 877; cost of (Py Q), 933; and medical women (Py Q), 1194
 Boas, Dr. H., abortive treatment of syphilis, 811
 Body-fluids, acid-base equilibrium of, revised nomenclature, 613
 Body heat and efficiency, 763
 Bodon, Dr. C., intracranial injection of adrenalin, 586
 Bognor War Memorial Hospital, report, 1054
 Bonney, Mr. V., diurnal incontinence of urine in women, 1214
 Boot and shoe trade, health in (Dr. F. W. Burton-Fanning), 108
 Bordier, Dr. H., Diathermie et Diathermotherapie (review), 82
 Borradaile, Dr. L. A., Animal and its Environment (review), 903
 Bory, Dr. L., Les Phénomènes de Destruction Cellulaire (review), 83
 Bosanquet, Dr. W. C., and Dr. G. S. Wilson, Green's Manual of Pathology and Morbid Anatomy, thirteenth edition 1923 (review), 903
 Bose, Sir J. C., Physiology of the Ascent of Sap (review), 657
 Boston City Hospital, report, 264
 Bottles, medical, manufacture of, 680
 Botulism and Food Preservation (Dr. G. Leighton) (review), 1061
 Botulism, a rare disease (leading article), 550
 Bourne, Mr. A. W., treatment of vaginal discharge, 397; hyperthyroidism as a cause of severe uterine hæmorrhage, 1210
 Bousfield, Dr. P., The Omnipotent Self (review), 704
 Bowel disease among miners in the tropics, 1173
 Bowman lecture on ocular aspects of pituitary body disorders (Dr. G. de Schweinitz), 912
 Boxwell, Dr. W., brain sarcoma, 957
 Bradford, Lady, and others, Royal Medical Benevolent Fund Guild, 305
 Brady, Dr. L., mesenteric vascular occlusion, 347
 Brain as a secreting organ (Sir J. Bland-Sutton), 1143
 Brain, History of Surgery of (Thomas Vicary lecture by Sir C. Ballance) (review), 29; Abscess (Dr. W. P. Eagleton) (review), 1062
 Brainard, Miss A. M., Evolution of Public Health Nursing (review), 189
 Braithwaite, Mr. J. O., and Mr. C. H. Hampshire, Year Book of Pharmacy (review), 84
 Bramwell, Dr. B., proposed testimonial to, 148, 160
 Bramwell, Dr. J. C., heart-block, 598
 Braxy, the nature of, 197
 Breakdowns of middle life (Dr. R. F. Fox), 55; and lowered immunity, 820

A Statistical Inquiry

INTO THE
EFFICIENCY OF PRESENT-DAY METHODS OF
DIAGNOSIS OF ULCERS OF THE
STOMACH AND DUODENUM,
AND INTO THE VALUE OF GASTRO-
JEJUNOSTOMY IN THEIR
TREATMENT.

By ARCHIBALD YOUNG, M.B., C.M., B.Sc.,
F.R.F.P.S. GLASG.,

PROFESSOR OF SURGERY AND DEAN OF THE MEDICAL FACULTY,
ANDERSON COLLEGE OF MEDICINE, GLASGOW; VISITING
SURGEON, WESTERN INFIRMARY, GLASGOW.

With the Collaboration of

ANDREW J. HUTTON, M.B., CH.B. GLASG.,
ASSISTANT SURGEON, WESTERN INFIRMARY, GLASGOW,
AND

JOHN SCOULER BUCHANAN, M.B., CH.B. GLASG.,
SURGEON TO OUT-PATIENTS, WESTERN INFIRMARY.

ON the evenings of Dec. 3rd and 17th, 1920, there took place, in the Royal Medico-Chirurgical Society of Glasgow, an important discussion on the treatment of gastric and duodenal ulcer. Of the many points of interest and value which emerged in the course of the discussion this inquiry is concerned with two only: (1) the supposed inherent difficulty in, and the unreliability of, the diagnosis of these lesions; and (2) the efficacy or not of gastro-jejunostomy in their treatment.

So much at variance did I find myself with some of the views on these points expressed on the first evening of the discussion that, in the interval before resumption of the discussion on Dec. 17th, with the aid of my assistants, Dr. A. J. Hutton and Dr. J. Scouler Buchanan, I set on foot a careful inquiry into both subjects, in respect of all such cases seen and dealt with by us within the three and a half years immediately preceding. It was intended to lay the results of the inquiry before the Society at the second meeting, but the interval of time was not long enough for completion of the investigation or for adequate digestion of its results. These results are presented, therefore, for the first time in this paper. It was also intended to extend the inquiry to cases further back than the period mentioned, but the findings for the latter seemed to us so gratifying and so conclusive that such further investigation has not appeared to be necessary. Nor was it deemed advisable to include the considerable number of similar cases dealt with since December, 1921, as the period that has elapsed was too short to give reliable data as to the permanency of the effects of treatment.

METHOD OF INQUIRY.

When the inquiry was set on foot we felt uncertain how far, if at all, its results might be at variance with views expressed in the earlier part of the discussion. The inquiry was made in as impartial a manner as possible, and with the single desire to discover the truth as borne out by well-ascertained facts.

The first part of the inquiry consisted in a careful comparison in each case between the diagnosis made prior to operation and the actual finding at operation; or, in the cases not operated on, in as unbiased and judicial an estimate as possible of the most probable pathological condition present. The series included all those cases within the period mentioned, in which lesions of the stomach or duodenum were diagnosed, whether the diagnosis was verified at operation or not; it included, also, cases in which other lesions were suspected or actually diagnosed—such as cholecystitis, appendicitis, &c.—but which were proved at operation

to be lesions of stomach or duodenum, or combined with these. The facts in this section of the inquiry were easily available in our records, which have been kept with care.

For the purpose of the second part of the inquiry a form of questionnaire was sent out to all patients included in the series except those who were known to have died. Replies were received from almost all to whom the communication was sent, and the conclusions were based on these replies. The nature of the questionnaire will be indicated later. Of course, there is, and probably always will be, both a medical and a surgical aspect of the subject; this inquiry is made largely from the surgical point of view. It is realised, too, in the case of ulcer either of stomach or duodenum, that the surgeon usually sees, and has to deal with, the chronic ulcer. Except where the ulcer perforates, or bleeds in alarming fashion, the surgeon seldom has to deal with the acute ulcer—not that the chronic ulcer does not also bleed and perforate; probably, indeed, most perforating ulcers are of the chronic variety. Still, a considerable proportion of the cases of perforation and of grave bleeding, as well as many cases of less severe bleeding, occur where there is present what would be properly termed an acute ulcer, and many of these cases, even now, the surgeon does not see at all. No doubt some ulcers, of the acute type at first, pass later into the state and class of the chronic ulcer, which the surgeon may see. But it seems probable, and it is generally accepted, that many ulcers of stomach and duodenum are of the chronic class from their inception. It is no part of the purpose of this paper to discuss the factors which determine the variation in type. The matter is mentioned merely as indicative of our appreciation of the fact that our conclusions have only a limited application. Within the limits set, however, we believe they are of some value.

DIAGNOSIS OF ULCERS OF STOMACH AND DUODENUM.

Much stress has been laid, in medical and surgical literature, on a supposed inherent difficulty in the diagnosis of these lesions, and the emergence of this idea, in the course of the discussion referred to at the beginning of this paper—with the reflection it implied on the efficiency and reliability of present-day methods of investigation—suggested to us the advisability of looking into our statistics, to see what support or otherwise they might give to such a despondent view. In the course of the discussion Dr. G. Herbert Clark pointed out how ample were the means at the disposal of the physician and surgeon in the way of investigation, and indicated how real and reliable were the available aids to diagnosis. One speaker had stated that the results of physical tests and chemical methods were frequently wrong. Dr. Clark maintained, on the other hand, that the results were accurate; it was the deductions that were inaccurate. Our view, in fact—borne out, we submit, at least substantially by our statistics—is that, in the main, a tolerably accurate diagnosis can be made differentially between these and allied lesions.

For the purpose of the inquiry we have taken all the cases occurring during the three and a half years immediately preceding the date of the discussion, in which definite symptoms suggestive of lesions of stomach or duodenum were present, or in which, for whatever reason, such lesions were suspected, whether operation proved their existence or not. Also, we have included such cases as may have been diagnosed otherwise, but in which operation disclosed a lesion of stomach or of duodenum not previously suspected. The series includes 110 cases, which we have classified in groups, each group-title representing the diagnosis made—not necessarily the lesion found at operation or finally accepted as the correct diagnosis.

It is not intended to enter into any discussion of the details of the methods on which we depended in the making of our diagnosis in any of the cases, nor, indeed, to refer to these methods at all. They were just such as are at the disposal of any careful observer,

and included the usual careful physical examination, chemical and physical tests, as well as X ray methods. We would like to add, however, that we attach great importance to a very searching and discriminating consideration of the clinical history in every case. We make no apology for confining our inquiry strictly to the purely statistical aspect of the matter. That is, indeed, the purpose of the paper. If we can show that, as a matter of fact, an approximately or actually correct diagnosis was arrived at in a very large proportion of the cases included in the series, it seems to us that we have proved our case—viz., that we possess, in present-day methods—clinical and chemico-physical—efficient and, on the whole, reliable means for the accurate investigation of these cases.

It may here be stated that it is our custom to endeavour to make a definite diagnosis prior to operation, if there is one; and in any case where doubt remains after consideration of all the available facts, to note that doubt. The cases are studied and generally discussed with some care, and at least a tentative diagnosis is put forward. That being our custom in the wards, it follows that we have, in the records of the ward journals, with, on the one hand, the pre-operation diagnosis, and, on the other, the operation finding, in each case a fairly useful basis for the statistical inquiry made.

The diagnosis made in each of the 110 cases may be shown in tabular form thus:—

	Cases.
Gastric ulcer	9
In these no other lesion was suspected.	
Pyloro-duodenal ulcer	38
This group includes ulcers situated at or about the pylorus, whether beginning as ulcers of the stomach or ulcers of the duodenum, and, on the stomach aspect, affecting either lesser or greater curvature. We have long recognised the group as quite well-defined, easily differentiated clinically. We commonly speak of them as P.D.U.	
Duodenal ulcer	21
Here we include only ulcers diagnosed as involving the duodenum by itself. It will be observed that it is a much smaller group than the foregoing.	
Cancer of stomach, &c.	26
In this group cancer was definitely diagnosed or strongly suspected.	
Pyloro-duodenal ulcer or cancer	6
Here it was recognised that the diagnosis, as between a chronic ulcer of the pyloro-duodenal region and cancer, was doubtful.	
Visceroptosis, &c.	4
Stenosis of the pylorus (congenital)	1
Gastritis of simple nature	1
Adhesions after gastro-jejunostomy (two years before)	1
Cholecystitis, gall-stones, and probable duodenal ulcer	1
Cholecystitis, gall-stones (no P.D.U. suspected)	1
Appendicitis, acute (perforation diagnosed)	1

These groups may now be considered in more detail, showing what correspondence there was between the diagnosis, as made, and the definitely ascertained or probable lesion.

Nine Cases Diagnosed as Gastric Ulcer.

These cases may be further subdivided as shown in tabular form below. Considering this group as a whole, it is seen that of the 9 cases, 5 were submitted to the test of operation; the diagnosis of the lesion and of its location proved correct in 4, while in 1 case the ulcer was found in the duodenum. The physician had diagnosed it as gastric, but the probable error was suspected prior to operation, after perforation had occurred. Of the remaining 4 cases one was observed for a considerable time, and the diagnosis, agreed to by physician and surgeon, may be accepted as reasonably correct. In 2 other cases, both occurring in women, operation was impossible, but they were almost certainly cases of gastric perforation. In the 1 remaining case the after-course supported the diagnosis of a "pinhole" perforation of a gastric ulcer. So that though only half of the cases were actually proved by operation to have been diagnosed correctly, a more careful survey of the whole of the

cases in the group seems to justify our claim that in 8 out of 9 cases the diagnosis was probably accurate. And in the ninth case the error was appreciated or at least more than suspected prior to operation.

	Cases.
With perforation of ulcer and free peritonitis	2
In one the diagnosis was correct; in the other the location of the ulcer proved to be duodenal. The case was diagnosed as gastric in the medical ward, but after perforation had occurred the signs were judged to be suggestive of a duodenal rupture.	
Without perforation of ulcer	3
One not operated on, but diagnosis agreed to by physician. Two cases confirmed at operation: in one of these diagnosis of concomitant aneurysm of abdominal aorta also confirmed at operation.	
With grave hæmorrhage—ulcer of lesser curvature diagnosed	2
One confirmed at operation—incomplete perforation, coronary artery exposed, and perforated in the floor of the ulcer; in the other case the patient was in extremis and operation was not considered advisable.	
Doubtful perforation of gastric or P.D.U.	1
Patient in extremis; died one hour after admission to hospital; no post mortem.	
Doubtful "pin-hole" perforation of gastric ulcer or acute dilatation of stomach	1
After drinking bout; no operation; recovery after course suggesting a local peritonitis consistent with a "pin-hole" perforation.	

Thirty-eight Cases Diagnosed as Pyloro-Duodenal Ulcer.

In this group perforation had occurred recently in 8, being confirmed by operation. The remaining 30 included 26 cases in which operation confirmed the diagnosis as to condition and location. In 2 cases there was no operation (not advised, 1; declined, 1). In the other 2 cases the diagnosis was not upheld by the operation-finding (visceroptosis, 1; chronic appendicitis and cholecystitis, 1).

Considering this group as a whole it may be reasonably claimed that out of the 38 cases the presence of pyloro-duodenal ulceration, as diagnosed, was proved by operation in 34, though in 1 of these the ulcerative process was found to be, or to have become, cancerous. Both cases not operated on were almost certainly correctly diagnosed, more particularly the case in which operation was advised but declined; the whole clinical picture was beyond dispute and confirmed by X ray tests. It seems quite fair, therefore, to claim 36 correct diagnoses out of 38.

	Cases.
With recent or recurrent perforation of ulcer	8
All confirmed at operation as to the presence of pyloro-duodenal ulceration, but in 1 case of the 8 the ulcerative process proved to be, or to have become, cancerous. One case had perforated previously (two years before—said to have been of stomach then). The fresh perforation was just to duodenal side of pylorus.	
Without recent perforation of ulcer	30
In 26 operation confirmed the diagnosis. In 2 operation was either not advised or declined. In 2 operation negated the diagnosis.	

Twenty-one Cases Diagnosed as Duodenal Ulcer.

This group contained 14 cases of perforation, and 7 in which perforation had not occurred. Of the former, 10 cases were found to be definitely duodenal; in 4 the perforation was found to be pyloro-duodenal. In the 7 cases in which perforation had not occurred, operation proved the correctness of diagnosis in 4. The remaining 3 were not operated on—in 2 cases because the symptoms and signs were, though fairly characteristic, not regarded as urgent; in the third because the depletion of blood, from repeated hæmorrhages, seemed to make operation too great a risk. This patient had had an operation previously, some years before, elsewhere—probably gastro-enterostomy—on account of similar symptoms; the clinical picture in this case was unmistakable.

Surveying the whole group, it appears that of the 21, diagnosed as cases of duodenal ulcer, the correctness of diagnosis and location was established

at operation in 14. In 3 out of the 21 there was no operation, but all the facts pointed, almost beyond dispute, to correct diagnosis. In the remaining 4 cases, operation disclosed an ulcerative process not strictly duodenal in location, but more extensive, involving the pyloro-duodenal region. Even this error of, at most, 4 out of 21, and implying only a slight spread of the ulcerative process, can hardly be said to constitute a serious defect in diagnosis.

	Cases.
With recent perforation	14
In 10 confirmed as duodenal at operation. In 4 proved to be pyloro-duodenal by operation.	
Without recent perforation	7
In 4 confirmed as duodenal at operation. In 3 no operation; in 2 of these, symptoms not urgent, but clinical picture characteristic; in the 1 case remaining, diagnosis practically certain, but confirmation by operation negatived by severity of hemorrhages.	

Twenty-six Cases Diagnosed as Cancer of Stomach.

This group includes a majority where the definite diagnosis of cancer was made, and several cases in which this diagnosis, although not absolutely definite, was so probable as almost to amount to certainty. In this group the element of uncertainty can never be entirely eliminated; there must always be cases in which it can only be said that there is a strong—perhaps a very strong—suspicion of malignancy. In 15 cases out of the 26 the presence of cancerous ulceration, in varying stages of development, was demonstrated by open operation. In 7 of the 26 operation was not carried out. In 2 of these the condition was too advanced to admit of any form of operative interference; one died within a week, the other within a few hours of being seen. In the other 5 of these 7 cases operation was refused; in 4 of these, however, the clinical picture was absolutely characteristic, and a fatal issue was not long delayed. In all 4 there was definite tumour, with evidences of spread to the liver, &c.—so that the diagnosis cannot be considered doubtful. In the fifth case there was some doubt; malignancy was definitely suspected, but the possibility of a cholecystitis had been considered. The patient reported, two years after refusing operation, that she was quite well, had gained weight, and had no longer any symptom; so that it may be admitted that, in this case, a diagnosis of cancer of the stomach was not justified.

There remain 4 cases in which operation was carried out, but in which it disclosed no sign of cancer, though a diagnosis of probable cancer had been made prior to operation. Two of these 4 cases showed well-marked, more or less active, pyloro-duodenal ulceration, with stenosis of the pylorus, &c. In 1 case there were found some adhesions about the pylorus, and dilatation of the stomach, but no sign of any recent ulcer of the region. In the remaining case the finding of a definite cancer was confidently expected; the symptoms and signs were thought to be most suggestive of it. Nevertheless, no evidence of cancer was disclosed at operation; chronic appendicitis, tuberculous glands in the mesentery, some dilatation of the stomach, and other evidence of old pyloro-duodenal ulceration were found. Thus:—

In 15 cases diagnosis confirmed at operation.
In 7 cases no operation.

Of these, operation not possible in 2, but condition unmistakable; in 1, operation advised but refused; clinical picture, however, characteristic, and fatal issue not long delayed: in 1 case diagnosis not clear, but afterwards, as reported on two years later, indicated that the condition was not malignant.

In 4 cases operation did not confirm correctness of diagnosis.

Two proved to be simple pyloro-duodenal ulcer: 1 showed pyloric adhesions, &c.; 1 showed a complex condition, involving appendix, stomach, glands, and duodenum.

A general survey of this group of 26 cases, in which a definite or probable diagnosis of cancer of the stomach had been made, shows that the diagnosis was certainly correctly made in 17 (15 confirmed by operation, with the 2 in which operation was impossible but the condition unmistakable); it seems

justifiable, indeed, to assume that the diagnosis was probably correct in 21 out of the 26 (i.e., adding to the 17 the 4 in which, though operation was declined, the clinical picture was characteristic); that, finally, the diagnosis was incorrect in 5 out of the 26 cases (4 proved, at operation, to be simple, and 1 in which operation was advised but refused, but in which the subsequent history disproved the diagnosis of malignancy).

Perhaps the most striking point in connexion with this group is this—that in all four cases where the diagnosis was proved at operation to be erroneous, the confusion was with a condition of chronic pyloro-duodenal ulceration. Probably such a condition may pass, not infrequently, into the malignant phase. Again, chronic pyloro-duodenal ulceration, especially where it affects the lesser curvature in the region of the pyloro-duodenal junction, is often marked by great inflammatory thickening, amounting often to considerable “tumour” formation. Indeed, even at operation, it is not infrequently difficult enough to say definitely whether a pyloro-duodenal mass is inflammatory or of the nature of a new growth. It may be noted, too, that in all 15 cases where operation confirmed the cancerous nature of the condition, the disease was already well advanced by the time operation was carried out. In 2 of the 15 the cancerous process was located primarily on the lesser curvature of the stomach; in 1 case, what was thought to be the prime seat was located on the posterior wall. In 6 cases the pyloric segment was primarily involved; in the remaining 6 the disease was already so far advanced that no more than a guess could be made as to the probable primary seat of origin. Unfortunately, not even yet does the surgeon often see these cases early enough.

Six Cases Diagnosed as Pyloro-Duodenal Ulcer or Cancer.

In contrast with the last group, in which cancer was definitely diagnosed or strongly suspected, but in which 4 cases proved to be simple, this group comprises 6 cases in which, while no definite diagnosis was made, the possibility of cancer could not be excluded, though there seemed to be a fair probability of the lesion being simple. The group may be said to comprise two subgroups: (1) Three cases in which the test of exploratory laparotomy was applied; (2) three cases in which operation was recommended, but was declined. In the first subgroup were 2 cases in which, even at operation, the diagnosis remained in doubt; what was thought to be extensive chronic ulceration was found, involving the lesser curvature of the stomach and the region of the pylorus, with definite and considerable “tumour”; also a case, operated on by a former assistant, who reported that he found a condition very similar to this. The former 2 cases are reported on now, after three years, as completely well; the third case was operated on only six months before this inquiry was made, and is reported to be greatly improved. In the second subgroup, in which no operation was carried out, one patient reports himself as quite well after 17 months; a second, seen a few days before this inquiry, is apparently much better after a prolonged rest, holiday and simple treatment. He has gained weight and his strength has improved. He has now no symptoms of special note. The third case of this subgroup was seen two years ago; this is one of the very few cases in which no reply to the questionnaire has been received. Thus:—

In 3 cases exploratory operation carried out.

In all 3 chronic ulceration with “tumour”; all well to-day, 2 after three years, 1 after six months. Even at operation cancer not clearly negatived, but subsequent course rules it out conclusively.

In 3 cases operation advised but declined.

One patient well after 17 months; 1 patient apparently well after seven months; the third not traced.

A consideration of this group seems to bring out one rather remarkable feature—viz., that where the diagnosis as between chronic pyloro-duodenal ulceration and cancerous ulceration is doubtful, the odds

seem greatly in favour of the non-malignant lesion. Certainly in 5 out of the 6 cases the subsequent history appears to have pretty conclusively proved the simple character of what had been regarded as quite possibly a malignant condition. In 3 of the cases, even at operation, it was not possible by actual inspection and palpation altogether to exclude cancer, but the lapse of time would seem in them, as in the 2 cases not operated on that have been traced, to have finally proved their non-malignancy. This feature, brought out by consideration of the cases in this group, is of interest and importance as emphasising the great value of a right estimate of the probabilities in surgical diagnosis.

Four Cases Diagnosed as Visceroptosis, including Gastroptosis.

The following are the details of the cases in this group:—

- One, general ptosis suspected, with probable gall-stones. Ptosis confirmed at operation; gall-stones found and removed.
- One, general ptosis diagnosed, with possible cancer of stomach. Operation disclosed general ptosis of stomach, &c., but no cancer.
- One, general ptosis diagnosed, including gastroptosis. Had been operated on three years previously for floating kidney; no further operation advised at this time, but operation required a year later for appendicitis.
- One, general ptosis diagnosed, including gastroptosis and nephroptosis; also congenital cystic kidneys. Operation confirmed the diagnosis, but also disclosed the half-suspected presence of cholecystitis; for the latter the gall-bladder was drained.

In all four cases, then, ptosis of stomach and other organs had been correctly diagnosed. In one case only had there been a suspicion of cancer; this was negatived by operation. In none of the 4 cases was any evidence of gastric or duodenal ulcer found at operation.

One Case Diagnosed as Congenital Stenosis of Pylorus.

This case was that of a young child of 3½ months; operation disclosed no organic stenosis. The stenosis was probably spasmodic. The case is included in the series of cases dealt with in the critical survey of this paper as falling within the category and period. It may be noted, however, that it is, somewhat curiously, the only case within the period in which we have had occasion to make the diagnosis quoted, though in the years before and since the date-period marked for this inquiry we had occasion to see, and to deal surgically with, several cases of congenital hypertrophic stenosis of the pylorus: and in none of these was the diagnosis either difficult or erroneous.

One Case Diagnosed as a Pure Gastritis.

The patient, a young woman of 34 years of age, had had recurring symptoms for several years, but without any definite indications of ulcer. Her condition improved greatly under simple treatment, and when heard from a year later she reported herself as having continued well from the time she was under observation by us.

This happens to be the only case seen by us and recorded as a stomach case without indication of ulcer, but with some of the clinical effects common to ulcer as well as to simple stomachic disorder without ulcer. (The cases of gastroptosis come into another category, of course.) The physician and the medical wards would tell a different story. These records, it cannot be too clearly understood, are those of the surgeon and of the surgical wards.

One Case Diagnosed as Abdominal Adhesions, Two Years After Gastro-jejunostomy.

In this case medical treatment was advised and the patient reported "well" a year after.

One Case Diagnosed as Cholecystitis, Gall-stones, and Probable Duodenal Ulcer.

Here operation confirmed the correctness of the diagnosis, except that no active ulcer was found; old adhesions, however, were found between duodenum and gall-bladder.

One Case Diagnosed as Cholecystitis with Gall-stones.

The findings in this case were as follows:—

The gall-bladder condition and the presence of gall-stones were confirmed by operation; it was found, however, that there was also old pyloro-duodenal ulceration with resultant stenosis of the pylorus. Both lesions were relieved by operation, the one by cholecystostomy and drainage of the gall-bladder, and the other by gastro-jejunostomy.

One Case Diagnosed as Acute Appendicitis, with Perforation.

The findings in this case were as follows:—

Operation proved the diagnosis to be wrong, there being no appendicitis, but, in fact, a perforated duodenal ulcer. This was sutured and drainage was established. The patient did well and reported as "very well" two years later.

It seems worthy of special remark that this is the only case, occurring under our observation during the period under review, in which a duodenal perforation was mistaken for an appendix lesion. The case was seen after perforation had occurred, indeed some time after. And it is well known that, under these conditions, confusion must occasionally occur. So well recognised is this that one is constantly on the look-out for such a possibility, but as often happens with a patient very gravely ill after a perforation, and perhaps unable, either personally or through friends, to give anything like a clear history of the crisis or of the antecedent symptoms, the nature of the perforation must often be in some doubt, and mistakes will probably always take place occasionally. That in this series, containing, as it does, 21 cases diagnosed as duodenal ulcer, in 14 of which perforation had occurred, only this one case was wrongly diagnosed as being of the appendix, seems to us to support, rather than to discredit, our thesis that the diagnosis of these lesions can be made, as a rule, with a much greater degree of assurance than many writers and speakers would seem to be prepared to admit. It is worthy of note that the series contains no example of the converse error—i.e., in no case during the period covered by this inquiry did we operate on a patient for a supposed duodenal perforation and find the perforation to be of the appendix.

SUMMARY OF THE FOREGOING.

A survey of the 110 cases included in this somewhat limited but comprehensive series, as borne out by the details given in the more fully recorded digest above, shows that the diagnosis was correctly made in 94 cases. Of the 16 cases in which the diagnosis was not correct the error was not uniformly serious or material. Indeed, in some cases it was not easy to say that the term error ought to be applied to the discrepancy between the diagnosis made and the operation finding. Thus:—

Of 9 cases diagnosed as simple gastric ulcer, only 1 case was wrongly diagnosed, and even that one was recognised as duodenal (after perforation) prior to operation.

Of 38 cases diagnosed as pyloro-duodenal ulceration, only 2 were proved erroneously diagnosed, one being general visceroptosis, including gastroptosis, the other a case of cholecystitis and chronic appendicitis.

Of 21 cases diagnosed as definitely duodenal ulcer, 4 proved to be of another nature, but the error here could not be said to be of a serious order, the condition in all 4 being merely more extensive in location, and involving the pyloric region as well as the beginning of the duodenum—i.e., pyloro-duodenal ulceration instead of purely duodenal.

Of 26 cases diagnosed as certainly or probably cancer of the stomach, in only 5 did the diagnosis prove to be unjustified. In 4 of these 5 cases operation disclosed pyloro-duodenal ulceration (in one of them, complicated by other lesions); the remaining case, in which there was no operation, had an aftercourse which suggested that it was of the same order. At any rate, 5 cases only out of 26 diagnosed as certainly or probably malignant, proved to be non-malignant—not a very large or serious error, especially when put alongside the fact that in only one case out of the whole 110 was a malignant condition found where a simple condition had been diagnosed.

One case of supposed congenital stenosis of the pylorus was found to be of a simple spasmodic nature.

In one case of cholecystitis, with gall-stones, where duodenal ulceration was also suspected, there was no direct

evidence of the latter at operation, though some adhesions were found between duodenum and gall-bladder; while in another case of the same nature pyloro-duodenal ulceration was found where it had not been previously expected.

The remaining case of error was the last mentioned in the detailed report—viz., the case of perforation, in which the site of perforation had been diagnosed as in the appendix, but proved to be duodenal; no case of the converse error occurred in the series.

These, then, are the facts of this somewhat limited but at least tolerably comprehensive and illustrative series of 110 cases. As given above in detail, they are stated, to the best of our ability, in as fair and judicial a fashion as possible. The records on which they are based have been taken at face value, and we have desired to present them as accurately and fairly as possible, with no attempt to strain any point, or to claim as correct any diagnosis not fully borne out either by evidence disclosed at operation, by clinical signs and symptoms, or by ascertained facts of after-history. A sincere effort has been made to get at the real truth of the matter in every case, and we do not wish to claim more for the result of our inquiry than the undoubted facts and dispassionate weighing of the probabilities seem to justify. We submit the facts with a certain degree of confidence that they go a good way to justify our claim that the ordinary methods at the disposal of physician and surgeon, in the diagnosis of ulcers of stomach and duodenum, furnish, in almost every case, efficient and reliable means for recognition and differential diagnosis of these conditions, and that the fraction of error should generally be trifling. And we agree, in the main, with the contention of Dr. Clark, already quoted, that where error in diagnosis does occur, it is seldom or never due to any defect in the methods of investigation, physical, chemical, and clinical, at our disposal, nor to the erroneous or unreliable results of these tests, but almost always to inaccuracy in the deductions made therefrom.

Gastro-jejunostomy in the Treatment of Gastric and Duodenal Ulcers.

It has already been stated that, for the purpose of this part of our inquiry, we took steps to ascertain the later history of all the cases included in the series; this applied, therefore, to cases of cancer, as well as to the few cases of other conditions wrongly diagnosed. The questionnaire issued brought the information desired, and the replies were expressed in such a way as to greatly enhance the value of the evidence. We felt that in no other way would it be possible to say that the conclusions drawn were beyond suspicion. We might have relied on such information as was, in many cases, already at our disposal, such as our own records of the more immediate after-history. We might have supplemented such information by personal examination of whatever cases could be easily recalled for the purpose. As a matter of fact, we had evidence of this kind in many cases, and it served to confirm our new reports. But we felt that the only facts that would be accepted as completely credible were those derived directly from the patients themselves.

It will be seen presently that the questionnaire was very simple. Accompanying the form sent out was a circular letter couched in friendly fashion, but asking for nothing more than a plain and unvarnished statement of actual facts. A very gratifying number of replies was received. The questions asked appear as headings to the columns of the tabular list.

For the purpose of this inquiry we are not concerned with the replies received dealing with conditions—such as cancer of the stomach—other than simple ulcer of stomach or duodenum. The object of this part of the paper is to ascertain what value to attach to gastro-jejunostomy in the treatment of these conditions. We have extracted, accordingly, the facts concerning those cases of gastric ulcer, pyloro-duodenal ulcer, and duodenal ulcer which we had treated by means of gastro-jejunostomy, and in estimating the results we have endeavoured to weigh

up all the facts and indications of the patients' own reports, and having established a conclusion in each case by correlating the replies to all the separate inquiries in the questionnaire, placing the result, as estimated, in one of the following six categories: (1) complete recovery; (2) great improvement; (3) considerable improvement; (4) not much improvement; (5) doubtful or unknown; (6) death.

In arriving at our estimate in any case we have not been satisfied by a mere statement—e.g., of a simple affirmative—in reply to the third question of the questionnaire, in concluding that the case should be classed as a complete recovery. We have required that replies to other questions should bear this out fully—e.g., in the way of sustained or increased body weight, in respect to absence of pain or other symptoms, and in regard to ability to take ordinary food freely and without discomfort. This is borne out by reference to the tabular statement of the replies received.

The results of our inquiry are as follows, and they refer to 42 cases:—

Complete recovery	.. 28 cases	 66.6 per cent.
Greatly improved	.. 6 "	 14.3 "
Considerably improved	1 case	 2.4 "
Not much improved	.. 3 cases	 7.1 "
Doubtful	 1 case	 2.4 "
Death	 3 cases	 7.1 "

It will be seen from the above figures that, while complete recovery took place in 28 out of 42 cases in which gastro-jejunostomy was performed, or 66.6 per cent., the result of operation was to produce great improvement—up to the highest possible, as expressed in complete recovery, in 34 cases (i.e., 28 plus 6), or 80.9 per cent. Adding the "considerably improved" group also, the result works out at 83.3 per cent. Thus it may be said that over 83 per cent. of the cases were considerably improved, almost 81 per cent. were greatly improved, while 66.6 per cent. made a complete recovery.

Small Proportion of Unsatisfactory Results.

Against these figures there have to be considered 7 cases out of the total of 42 in which either death occurred, or not much improvement took place, or where the result was doubtful or unknown. Taking deaths first, in one case (gastric ulcer) death took place suddenly on the tenth day after operation from pulmonary embolism; the case had apparently proceeded satisfactorily up till that point. In the second case (pyloro-duodenal ulceration) the immediate result was good, but the patient died rather unexpectedly about two and a half months after the operation in a sanatorium, the cause of death being given as tuberculosis of the lung. In the third fatal case the operation included appendicectomy as well as gastro-jejunostomy, and there was no special difficulty; it was performed, however, during the height of the influenza epidemic, and the patient developed an acute influenzal bronchitis and broncho-pneumonia which led to death four days after operation.

The case classed as doubtful, the ultimate result being unknown, was that of a man who, prior to operation, had marked gastric tetany; the immediate result was a great improvement, but all efforts to trace the man after his dismissal from hospital have proved unavailing.

As regards the 3 cases where "not much improvement" has taken place, it may be confessed that their histories do not disclose any special reason for the failure.

The first was a man who had suffered for upwards of seven years from symptoms of pyloro-duodenal ulcer. He had great dilatation of the stomach, with ptosis of stomach and general visceroptosis. Also, he had many adhesions between the duodenum and gall-bladder. At operation it was noted that the first part of the duodenum was also greatly dilated. A little over a year after his operation he reported himself thus: "General condition slightly improved." *Complete recovery?*—"No; great headaches, as formerly, also flatulence." *Take food well?*—"Inclined to eat at any time—great thirst." *Pain?*—"Yes, very often in chest and back; no trouble with bowels; same weight as

TABULAR LIST OF CASES OF GASTRIC, PYLORO-DUODENAL, AND DUODENAL ULCER, SUBMITTED TO GASTRO-JEJUNOSTOMY, AND REPORTED ON IN THIS INQUIRY, WITH DETAILED ANSWERS TO QUESTIONNAIRE.

Case Classed as Doubtful.

P.D.U. = pyloro-duodenal ulcer. P. sten. = pyloric stenosis. Di. sto. = dilated stomach. Chr. = chronic. G.J. = gastro-jejunostomy. A. = appendicitis. U. = ulcer. Ay. = appendectomy.

formerly: occasional sickness, but no vomiting or bleeding; no bleeding by bowel or tarry motions." The only other fact in this case calling for special note is that he had a bad attack of bilateral parotitis during the early period following operation.

The second was a man of 36 years, who had had for upwards of three years symptoms suggestive of chronic pyloro-duodenal ulcer, with great dilatation of stomach. The diagnosis was confirmed at operation. This man's report after two years was almost altogether unfavourable; information of his condition was obtained from another hospital shortly before this survey was begun. He now had symptoms strongly suggestive of "gastric crises" of tabes; also a positive Wassermann reaction had been obtained. He had gained, however, over a stone in weight, and had frequent periods—six or seven weeks—of comparative freedom from sickness and vomiting.

The third was a man of over 60 years, who had had digestive trouble for over three years. His symptoms, borne out to some extent by the operation finding, rather suggested a chronic pyloro-duodenal ulcer (there was more than a suspicion of a malignant element). At operation a definite healed ulcer of the lesser curvature of the stomach was also found. The man was, however, in a poor state of health otherwise, with degenerated arteries, and more than a little inclined to mental depression, almost to melancholia. His report after operation gives the result, from his point of view, as not at all satisfactory: "Slight loss of weight; vomiting of bile (?); do not take food well; condition unchanged." His mental depression remains, and may have militated against recovery and coloured his interpretation of the result. In any case, the interval which has elapsed between the date of operation and the date of the estimated result seems altogether too short to admit of a reliable test of the treatment.

What may be regarded, then, as the failures, from whatever cause, comprise 6 cases out of the 42—three deaths and 3 cases in which no definite improvement was achieved as the result of gastro-jejunostomy. a percentage of, say, 14, against a percentage of 66.6 complete recoveries, of 81 above the "great improvement" line, and of 83.3 above the "considerable improvement" line. Moreover, in each case of death, the fatal issue may almost be ascribed to an accidental circumstance, so that the fatal issue in these cases can hardly tell against gastro-jejunostomy as a method of treatment in such conditions. It may fairly be contended that only the 3 cases of actual failure—"not much improvement"—ought to be considered in comparison with the great bulk of the series.

For comparative purposes the duration of symptoms in each case prior to operation and the length of the period between operation and the date of the report are here given.

Complete Recovery (28).

13 .. 10/12	4 .. 8/12	10 .. 3	7 .. 2	30 .. 3 1/12	4 .. 8/12	10 .. 3	7 .. 2

The average duration of symptoms in the 28 cases classed as having made a complete recovery was ten years; the verdict of complete recovery is based on an average period of observation, subsequent to the operation of gastro-jejunostomy, of one year and eight months.

Greatly Improved (6).

A = Duration of symptoms prior to operation, in years.
B = Period between operation and report, in years.

A	B	A	B	A	B
4 .. 10/12	10 .. 4/12	4 .. 2 7/12	5 .. 2 7/12	13 .. 10/12	2 .. 3

This table shows that the average duration of symptoms in the 6 "greatly improved" cases was 4 5/6 years, the average period following operation being one year and eight months.

Considerably Improved (1).

Duration of symptoms prior to operation: 1 year +
Period between operation and report: 2 8/12 years.
The figures here are: 1 year, and 2 years and 8 months.

Not Much Improved (3).

A = Duration of symptoms prior to operation, in years.
B = Period between operation and report, in years.

A	B	A	B
7	1 2/12	3	4/12
3 (+)	2 2/12		

The average duration of symptoms prior to operation of these 3 "not much improved" cases works out as 4½ years; the average period of observation subsequent to operation was one year and two months.

Doubtful (1).

Final result unknown, though early result satisfactory.
Duration of symptoms prior to operation: 2 years.

Deaths (3).

Estimated duration of symptoms prior to operation: 5, 5, and 15 years.

The average duration of symptoms prior to operation in these 3 cases ending fatally was thus six years.

Conditions for which Operation was Performed.

The following list shows in tabular form the conditions for which the operation was carried out in the group of 42 cases.

It may be noted that in only one case was the anterior operation employed. In 41 cases the method followed was the usual posterior gastro-jejunostomy, by the "no loop" procedure. In none of the cases was the pylorus either constricted deliberately or divided. We believe that closure of the pylorus is neither necessary nor indeed advisable; we are almost prepared to contend that it is not justifiable on any physiological ground. Nor do we believe that it is of value as a preventive of the much-talked of and dreaded "bilious vomiting." We are able to record here that out of the whole series of 42 cases in only 3 did "bilious vomiting" occur.

Gastro-jejunostomy alone (33 cases):

Gastric ulcer	1	Duodenal ulcer ..	4
P.-D. ulceration	28		

Gastro-jejunostomy plus suture of a perforated ulcer and peritoneal drainage (3 cases):

P.-D. ulceration	2	Duodenal ulcer ..	1
------------------------	---	-------------------	---

Gastro-jejunostomy plus appendicectomy (4 cases):

P.-D. ulcer plus	3	Duodenal ulcer plus ..	1
appendicitis		appendicitis	

Gastro-jejunostomy plus cholecystostomy (2 cases):

P.-D. ulcer (chronic) plus cholecystitis (gall-stones), 2.	
--	--

Bilious Vomiting as a Complication of Gastro-jejunostomy.

It may be noted that of the 3 cases in which "bilious vomiting" occurred, in one this complication seemed to be related in some way to a renal calculus, which was passed about three weeks after the operation; the vomiting became very infrequent thereafter, and in a few months passed off altogether. In the other 2 cases it persisted for the period which the observation covered.

One of the two was the case already referred to as "not much improved," in which, later on, evidences of tabes presented themselves, with gastric crises, positive Wassermann reaction, &c. The other case was that of a man suspected of having cancer of the stomach, who had had symptoms of chronic ulcer for upwards of three years. Operation disclosed the presence of chronic pyloro-duodenal ulcer, with stenosis of the pylorus and adhesions; also great dilatation of the stomach. The healed ulcer at the pylorus region was chiefly on the lesser curvature. In this case the time between operation and date of report was very short, and improvement, both as regards bilious vomiting and in other ways, may still be looked for.

In general, our conclusion on the subject of the "bilious or regurgitant vomiting," of which so much has been written in connexion with gastro-jejunostomy, is that this much feared complication very rarely occurs, and, indeed, should not occur, where the operation is performed for some gross organic lesion of the pyloro-duodenal junction, and where the "no loop" method of operation is

used. The possibility of such a complication seldom enters our calculations in respect of any case with which we have to deal.

It may here be mentioned—although it does not concern the purpose of this present survey—that the operation of gastro-jejunostomy was carried out by us in a considerable number of other cases—such as gastric cancer—otherwise inoperable, and with satisfactory results in the direction of palliation. Its applicability in such conditions cannot be disputed, nor can its beneficial effects be denied. We met with no "bilious vomiting" amongst the cases of gastric cancer in which it was employed.

ADDENDUM BY A. Y.

As indicated above, the survey applies to a series of cases within a comparatively short and well-defined period of three and a half years, the detailed particulars regarding which have been easily available for reference. In nearly all cases where gastro-jejunostomy was performed within this period, on account of gastric, pyloro-duodenal, or duodenal ulcer, the details of the immediate aftercourse have been known to us, and the later progress has been ascertained in response to the questionnaire. It may be of interest—it may even be necessary—to say that the figures do not represent anything like the total number of cases that might have been drawn upon by myself or my helpers for the purpose of statistical comparison. They form, however, a sufficiently representative and self-contained group, capable of consideration within workable limits, and are put forward on that footing.

A very brief note may be given here of the statistics relating to other occasions upon which I have performed the operation of gastro-jejunostomy—both before the period under review and subsequently—for just such conditions as are referred to in this survey—viz., ulcers of the stomach and duodenum. About a third of these were carried out in the Broadstone Jubilee Hospital, Port Glasgow; the remainder were in the District Hospitals, Glasgow, in the Western Infirmary, Glasgow, and in private practice.

The number does not include any of those other operations on stomach or duodenum, such as gastrotomy, pyloroplasty, pylorodiasis, pylorectomy, partial gastrectomy for chronic ulcer or cancer, or any of the large number of operations for simple perforation of stomach or duodenal ulcer. Nor does it include any cases in which gastro-jejunostomy was performed as a palliative procedure in otherwise inoperable cancer of the pyloric segment, although I have done a considerable number of such operations. The numbers apply exclusively to cases where gastro-jejunostomy was performed for simple ulcer and its near or remote effects. As to the results, these are known only in a general way, but I believe they are, and have been, certainly not inferior to the results in the more detailed series presented above. In none of them was there bilious regurgitation of any consequence; indeed, it occurred in only one case, and was transient and negligible.

The operation was carried out for the following conditions:—

	No. of cases.
1. Gastric ulcer	2
2. Pyloro-duodenal ulcer (P.D.U.)	36
3. Duodenal ulcer	11
4. P.D.U., combined with appendicitis (appendicectomy carried out at same time)	4
5. P.D.U., where an old gastro-jejunostomy opening had become contracted (a new gastro-jejunostomy being made)	1
6. Hour-glass stomach, resulting from chronic ulcer of the lesser curvature (gastro-gastrostomy being done at the same time as the gastro-jejunostomy)	2
Additional total	56

Of these additional 56 cases three died. In one, a case of duodenal ulcer, death occurred from syncope soon after operation. Two deaths were due to pneumonia, both being cases of pyloro-duodenal ulcer; one of them died on the third day from an acute broncho-pneumonia, the other from an ordinary lobar pneumonia on the fourteenth day after operation.

THE AFTER-EFFECTS OF WAR
NEPHRITIS.¹By G. L. THORNTON, M.C., M.R.C.P. LOND.,
M.R.C.S. ENG.LIEUT.-COLONEL, R.A.M.C. (T.A.); DEPUTY COMMISSIONER OF
MEDICAL SERVICES, MINISTRY OF PENSIONS.

THE subject of this paper has deservedly attracted considerable attention during the past seven years, and while for the first four of these years we were menaced with a disease which had the effect of rendering a very serious number of men permanently unfit for the fighting line, our interest has subsequently been maintained in the study of the after-effects as related to the resumption of ordinary civil employment. When the paper was originally communicated in a fuller form to a medical society the first part comprised a personal narration of cases of acute nephritis as observed when they first reported sick with symptoms of that disability. In view, however, of the extensive nature of the literature already set forth concerning the earlier stages of the affection, it has been thought best to confine this publication to the second portion of the original paper, which deals mainly with the after-effects. The deductions which follow have been drawn from the study of 100 unselected cases of ex-soldiers examined in respect of their claims to pensions for nephritis at periods ranging from eight to three years after the onset of that disease.

General Scheme of Inquiry.

The investigation was originally instituted with a view to following up the significance of tube casts, a subject in which I had been interested several years before the war, but it seemed to me that a more general inquiry might be of value, and although I have personally investigated the urine in all cases, I am indebted to Drs. F. R. Bremner, F. A. Roper, T. R. C. Whipham and J. White, of the Ministry of Pensions Medical Boards, for the greater number of the systemic examinations. The general scheme of the inquiry adopted for the whole of the cases has been tabulated so as to distinguish officers and other ranks; among the former are included the particulars of one nursing sister. The age at onset, date, and locality have been noted wherever possible. The systemic examination has been noted under separate headings for A.C.D., impulse, cardiac sounds, pulse-rate, and description of arterial wall, blood pressure, oedema, condition of lungs, and general remarks, including a summary of the man's incapacity without entering into any detail of figures which should rightly be a matter for official returns alone.

The routine examination of the urine has included estimation of urea, calculation of the diastatic index, estimation of albumin (where present) by Esbach's albuminometer, and the microscopical examination of the centrifuged deposit. The methods of MacLean have been followed in estimating urea—viz., by giving 15 g. urea by mouth immediately after the patient has emptied the bladder. This amount is noted as also the amounts voided after intervals of one and two hours. The third voiding is, as a rule, selected for estimating the urea. We can thus place some value on the figure of the N. excretion and gauge the degree of polyuria if present.

In this series of 100 cases, examinations relate to four officers and one nursing sister, but it would not be a fair deduction to take account of the proportion, in that the figure represents all officers examined for nephritis since demobilisation, whereas the analysis of the reports on the men is not based upon the total number who have passed through the hands of boards. The true figure would be considerably below the average proportion of officers to men in a battalion. Table I. shows the age incidence of four officers, one nursing sister, and 100 men from the series.

¹ Based upon a paper read before the Devon and Exeter Medico-Chirurgical Society.

TABLE I.

Age.	Officers.	Nursing sisters.	Men.
Under 20	—	—	6
20-25	3	1	17
25-30	—	—	23
30-35	—	—	21
35-40	—	—	20
40-45	—	—	9
45-50	1	—	4
Totals	4	1	100

The chief point for comment in Table I. lies in the comparatively low figure of the 20 to 25 period for men—an age which would be well represented in the line after the first year of the war. The officers' figures are too small for comparison.

CHART 1.

Illustrating month of onset in 100 cases of nephritis, 1914-1920.

Date of Onset. (See Charts 1 and 2.)—It is worth noting that two of the cases occurred in 1914—one in August, the other in October—for some writers have regarded nephritis as almost unknown in the army during the war until 1915. One of these cases, aged 33, was a reservist, R.A.M.C., and had been working as a clerk in civil life. He contracted nephritis in August, 1914, during the retreat from Mons, and informs me that, in spite of the month, he suffered much exposure at night during this period. The charts show the gradual rise from 1914-15, and the steeple ascent to 1917, when the climax was reached. In 1919 appear the effects of cessation of active warfare combined with demobilisation.

No useful figures can be given as to locality, but the cases are drawn from every theatre of war with exception of East Africa. Cases occurring in the Royal Navy represent only 2 per cent. of the series.

History of Onset.—This is difficult to obtain with any accuracy, as we must frequently rely on the man's own statement, except for the brief diagnosis on Army Forms B. 103 and 178. Worthy of mention are the following examples: Diarrhoea; laryngitis with bad cold; influenza (?); bronchitis; invalided home with bronchitis—on mined hospital ship—exposure in water—nephritis; followed trench fever; onset with shivering and tender loins; still has attacks resembling P.U.O. (T.F.); trench fever and bronchitis. Two cases of aggravation originally occurred, one after "purpura," and the other after "acute rheumatism"—recorded in documents.

Cases severe at onset are occasionally recorded. Most marked are: (1) Nursing sister, aged 28 at onset, October, 1917, France. Uræmic convulsions and general oedema; still greatly incapacitated. (2) Gunner, R.G.A., aged 40, onset 2/3/17, France. Uræmic fits, general oedema, venesection; mild to moderate incapacity now. (3) Private, R.A.F., aged 34, onset February, 1917, France. Severe onset, suppression, hæmaturia; mild to moderate incapacity now.

Subjective Symptoms.—Headache in a large proportion, and frequent accompanying dizziness; breathlessness in about one-fifth of cases; vomiting 7 cases; hæmaturia (intermittent) in a very few cases—2 at least of which have subsequently been rediagnosed as calculus. Neurasthenic symptoms have been fairly frequent.

General Appearance.—Thirty per cent. have shown very little or no evidence of anæmia or debility. Anæmia has been noted to a moderate extent in about 45 per cent. Twenty-five per cent. have shown evidence of dilated capillaries—marked anæmia, dyspnœa, &c.—sufficient to stamp them at once as greatly incapacitated. Several have shown emaciation, and a general condition which has suggested reference to the tuberculosis officer for observation.

Systemic Examination.—Increase in the area of cardiac dullness was noted in 34 cases, but in only

identical case; same age, onset 1916. The cardiac condition is even less satisfactory, auricular fibrillation having developed recently.

Edema.—This has been difficult to estimate accurately, as it so frequently clears up in mild cases a short time after rising, and we have then only the man's own statement as evidence at time of examination. Twenty-seven have, however, showed slight indication, such as puffiness of the eyelids and slight pitting of the feet and ankles; six showed moderate evidence, and two considerable.

Lungs.—Pulmonary complications have not been common—seven were found to have rhonchi and moist sounds at the bases, and in one there are suspicious physical signs at the left apex.

Eye.—It had not been practicable to obtain a routine examination of the fundus, although Dr. G. P. Hawker has kindly investigated one or two suspected cases, but as far as I am aware no gross lesion has been found in any case in this series.

Urine.

Volume.—It is, of course, impossible to obtain an exact measurement of the 24 hours' output in the majority of these examinations, but MacLean's urea test and the measurement of voidings, one or two hours after ingestion of the urea, provide useful information, particularly perhaps in that urea, having a slight diuretic influence, measurements below 300 c.cm. can be regarded as indication of absence of polyuria. Men's statements are, of course, often unreliable, and the frequent assertion, in the words of the Psalmist, that a man's reins chasten him in the night season, has often been unsupported by evidence of polyuria at the time of the examination or by the presence of albumin or casts. In 51 cases there has been evidence of some increase, and in 49 no evidence. The largest measurement was noted personally on Feb. 11th, 1922. This man passed a total of 1455 c.cm., 180 c.cm. to empty his bladder, and 1275 c.cm. in one or two hours after the urea test. He is aged 42, was wounded and gassed in France, and found to have nephritis on admission to hospital. He now shows considerable circulatory embarrassment in addition to evidence of contracted kidney. There was no reduction of Fehling.

Specific Gravity.—This is unreliable as ascertained at one short period of the day, but taken for what it is worth the average has not exceeded 1010.

Albumin.—The nitric acid ring test has been employed in all cases, and except where the merest trace has been under consideration the amount has been estimated with Esbach's albuminometer. Albumin has been found present in 65 per cent. and absent in 35 per cent.

Cases.	Estimation (Esbach's scale).	Cases.	Estimation (Esbach's scale).
51 ..	below 0.05 %	1 ..	below 0.15-0.2 %
6 ..	.. 0.05-0.1 %	3 ..	.. 0.25-0.3 %
4 ..	.. 0.1-0.15 %		

In 51 cases, therefore, the reading is low and represents little more than traces, but at the risk of appearing pedantic I would call attention to the common error of not appreciating—when calculating percentages—that Esbach's instrument represents grammes per litre.

Urea.—Estimation of urea is, needless to say, of little value when undertaken with a casual sample, but the method devised by MacLean provides a very fair appreciation of the efficiency of nitrogen excretion in a large number of cases, and checked by the diastatic reaction we are able to comment further on those cases where the excretion percentage has fallen low owing to diuresis. Hypobromite of soda solution has been freshly made for each case, and the instrument used has been the modified Doremus with tap. Albumin where present has always been separated from the sample for estimation of urea.

The following are the readings in 110 cases:—

Urea.	Cases.	Urea.	Cases.
Under 0.5 %	3	Under 1.5-2.0 %	29
.. 1.0 %	16	.. 2.0-3.0 %	26
.. 1.0-1.5 %	25	.. 3.0-4.0 %	14
Average for 110 cases—1.8.			
62			

CHART 2.

Illustrating year of incidence in 100 cases of nephritis.

two cases was the apex beat found outside the mid-clavicular line. In 86 cases where the impulse has been accurately noted this has been located in the fifth space in 80 instances and in the sixth space in six. Variations in the first sound have been reported in 29 cases, and accentuation of the second sound in the same number. Murmurs, chiefly apical systolic, have been recorded in 10 cases. One case has developed an aortic diastolic murmur, and in another of some uncertainty, not included in the series, nephritis is supposed to have preceded aortic disease. I have lately made use of the differential stethoscope (Leyton's original pattern) in reviewing a few of the more serious cases, and the readings tend to show a considerable increase in the intensity ratio on the part of the second sound, but with a loss of not more than 20 per cent. in the value of the first sound. The pulse-rate requires no special comment, except that it is by no means easy to gauge accurately at a medical board, when the man is frequently over-anxious and excited.

Arterial Wall.—This has been found thickened in 45 cases. Descriptions vary somewhat at different fingers, so that it would be misleading to give the sub-classifications of the various observers of the series.

Blood Pressure.—This has been noted under 110 in 1 case; 110-120 in 3 cases, 120-130 in 11 cases, 130-140 in 17, 140-150 in 33, 150-160 in 21, 160-170 in 4, 170-180 in 2, and 190-200 in 1 case. One case was found to have a blood pressure of 260 and another of 230. The case with 260 is now aged 50; onset of nephritis, July, 1918; area of cardiac dullness increased three-quarters to right apex beat in sixth interspace; systolic murmur at apex; arterial wall greatly thickened; urine, sp. gr., 1010; albumin, 0.05 per cent. (Esbach); urea, 1.0 per cent.; diastatic index, 2; granular and hyaline casts in every field. The case with blood pressure 230 relates to an almost

It has been calculated that the percentage of urea passed one to two hours after ingestion of 15 g. of urea should be from 2 to 4 per cent.

Diastatic Index.—This has been ascertained in all but a few cases where the urea excretion was within normal limits and other signs negative. Here again the test is of greater reliability if undertaken with the mixed urine of 24 hours, but nevertheless the information obtained from an examination sample is of considerable value as a control to the urea estimation, and in these 100 cases the reading has generally coincided with the general clinical feature of the case, whereas the urea has not infrequently proved the only sign of ill-omen. I can find no instance where the diastatic index was normal in severe cases, where, as Dr. F. A. Roper has reminded me, we should consider the possibility of pancreatic disease and carry the test further than the 20-unit tube, which proves sufficient for a gauge of renal efficiency alone.

I give the following figures for 93 cases in the series:—

Units.	Cases.	Units.	Cases.
1	1*	6.6	23
2	6	10	34
3.3	16	20	13

Average=8.7 units.

* Urea 0.2; diuresis very great, severe case.

For comparison with the urea test the average urea percentage has worked out $\frac{1.8}{8.7}$.

diastatic index $\frac{U}{D} = \frac{3}{20}$.

The calculation has been carried out invariably with freshly prepared starch solution, and the starch obtained from the same reliable source—with this provision there is little risk of error if caution is applied in dissolving the starch—and one is only content with a clear solution.

Tube Casts.—These have been noted in 49 cases, and have been sought for with extreme care. In my opinion this figure should be considered a low estimate owing to the fact that in many cases where diuresis has been moderate or excessive a negative finding should not be final, and in all probability the examination of the centrifuged deposit of the mixed 24 hours' urine would bring this percentage appreciably higher.

Differentiation of Casts.—Hyaline casts alone were noted in seven cases, and with granular or in association with epithelial or blood casts in 44 cases. Blood cells (as a rule a few scattered red blood cells) were found in association with casts in 19 cases, but true blood casts symptomatic of acute or subacute relapses have been rarely found. Casts were found unassociated with albumin in eight cases, and albumin (not exceeding a trace²) was noted in 31 cases, where casts could not be found in the urinary sediment. The urine was examined fresh from the mixed samples and as a general rule after four minutes centrifugalisation. A general summary of the cases where casts were found in the urine shows in table form that where hyaline casts alone were noted the sum-total of the findings demonstrated an incapacity ranging from very slight to moderate—the tendency being to slight.

Capacity for Work.

A general summary of cases as regards their capacity for work, based upon the sum-total of the systemic examinations and urine analysis, is as follows:—

Very slight incapacity	20
Slight to moderate	49
Considerable	17
Only fit for lightest occupation	8
Total incapacity	1
Died	1
Uncertain	4

100

Table II. shows the association of casts and albumin or negative findings of the same in these various

² Larger amounts of albumin were found in cases where the diagnosis was found to be pyelitis or cystitis, but these are not included in the series.

TABLE II.—Illustrating the Degree of Incapacity in Cases where Casts and Albumin were Present Together, Present Singly, or Both Absent.

Incapacity.	Hyaline casts only.	Mixed casts. No albumin.	Albumin and casts.	Albumin and no casts.	No casts and no albumin.	Total.
Very slight	2	2	3	3	10	20
Slight to moderate	3	5	18	18	5	49
Considerable	—	1	5	9	2	17
Only fit for light occupation	—	—	7	—	1	8
Total incapacity	—	—	1	—	—	1
Died	—	—	1	—	—	1
Uncertain	2	—	1	1	—	4
Totals of cases	7	8	36	31	18	100

grades of incapacity. These deductions are merely drawn from the study of 100 unselected cases of ex-Service officers and men who have been examined for their invaliding disability of nephritis; they nevertheless represent a very fair proportion of the total number of cases under observation in this area (the S.W. of England), and whilst the general findings will, I consider, give a just insight into the present condition of the average case, the mortality figure reads low in comparison with that of 2.5 per cent. obtained from all known cases in the district.

To sum up, acute nephritis is a rare disease in civil life; we know very little of its aetiology, save that it has been associated with a variety of infections, and that frequently there has been, in addition, the history of exposure. During the war it was at one time sought to prove that one particular micro-organism was responsible for the epidemic nature of the disease as occurring at that period, and that clinically the affection was something apart from the acute nephritis we saw so very occasionally at home. There, I think, lies the fallacy; we never saw sufficient acute nephritis prior to the war to allow us to appreciate the wide range in severity of the cases. We have learnt nephritis from the war. The mild or moderately severe type of case at onset appears to have been common, but we can find many examples of a severer form—some of them I have quoted in this paper—in all ways comparable to cases seen in civil practice. I know of an athletic young woman, who 12 years ago had an extremely severe attack of acute nephritis, and for weeks appeared to be drifting into a hopeless condition of chronic tubal nephritis, with general oedema; to-day she cannot be said to be absolutely sound, but she can hold her own in competitions requiring a considerable output of physical energy. Cases occurring in civil life in the same way as those under contemplation show that a hasty prognosis, based either on the mild or severe nature of the initial symptoms, will frequently prove erroneous in the light of the subsequent history.

The course of the severer cases seems to be comparable—why not the mild also? Is it not possible that we never see some of the mildest cases in home practice?—just as abroad so many were diagnosed quite accidentally. Again, does all the acute nephritis seen at home account for the apparently commoner case of chronic tubal nephritis?

Causation.

As regards causation we find no solid reason for divergence in the two instances. Overseas we were constantly faced with varied infections—P.U.O., trench fever, tonsillitis, influenza, acute rheumatism, the exanthemata, &c., and exposure provides a well-laid ground for the sport of secondary infections. The part played by exposure must be acknowledged; officers are undoubtedly affected in numbers considerably under their strength in proportion to men; native troops with their loin protection were less vulnerable than Europeans even when fighting in the climate of the latter; Highland troops provided fewer cases, and perhaps because of the kilt fitting snug to the hip.

A study of these figures shows that the trained soldier also suffered far less than the man of the new army. The trained soldier was accustomed to sleeping out in all weathers, and to get the last calorie out of his kit; he was educated into attaching more value to depth underneath than to weight above. The temporary soldier, on the other hand, was new from sleeping on a heavy mattress, and no doubt frequently with closed windows; he felt the cold and crammed every available rag on the top of himself, ignoring his back and inviting chills. The untrained man of over 30 proved especially inelastic to radical changes in his mode of life.

The effects as evidenced to-day cannot be lightly set aside either, as they influence—and are likely increasingly to influence—the comfort and wage-earning capacity of the individual concerned; or as they are considered in the light of the State provision which must be made in fair compensation for the same. In warfare we cannot expect to dispose altogether of the problem of exposure. Camp discipline and some general form of military training, if made possible for the youth of the nation, would at any rate render them more prepared for eventualities; any experiments would seem worthy of consideration if undertaken to counteract exposure, which, in spite of all that we have learnt from pathology and bacteriology, still remains a powerful factor in the causation of disease.

I have to thank the Director-General, Medical Services, Ministry of Pensions, for permission to publish these notes.

REFLEX DULLNESS IN OLD CHEST WOUNDS.

By A. NEVILLE COX, M.D., M.R.C.P. LOND.,
TUBERCULOSIS OFFICER, BRIGHTON.

C. Riviere¹ has described in cases of phthisis bands of impaired resonance to gentle percussion across the lower scapular region on both sides of the back, about the level of the fifth to seventh dorsal spines, which he terms "reflex bands of dullness." He states that in a healthy person they are absent, but can be made to appear for a time by forcible percussion of the front of the chest; that they are present in otherwise healthy subjects in whom there is marked *nasal obstruction*; and that, in the absence of nasal obstruction, the persistent presence of these bands of dullness "denotes an irritation (? always inflammation) of the lung parenchyma of some causation not necessarily tuberculous" and "will help to decide the presence or absence of a hidden focus in a case suspected of early tubercle, and they are useful in the exclusion of all catarrhal conditions not involving the lung parenchyma."

Some observers are frankly sceptical not only as to the interpretation, but even as to the existence of these bands of dullness. Those who invariably practise heavy percussion are not likely to find them. Most physicians who examine many chests will probably agree that there are areas of impaired resonance in early cases of phthisis which cannot well be due to anatomical change in the lung substance; they are too extensive, or are found on both sides of the chest when the only other evidence of disease is unilateral. Since reading Riviere's paper I have made it a practice to search for "band dullness" as a first step in the routine examination of all lung cases. It should be the first step, because the necessary manoeuvres in the later examination of the patient may in themselves cause the sign to appear. It is also necessary to observe whether the patient has nasal obstruction. In practice it is sometimes difficult to be sure whether the band dullness is present. The cases fall into three groups: (1) Where the sign is certainly present; (2) where it is certainly absent; and (3) the doubtful

cases. Greater experience, or a nicer discrimination in touch and hearing, would very probably enable one to eliminate the doubtful group.

Symptoms Resembling those of Phthisis.

In examining patients for this sign I have as far as possible avoided all bias as to the likelihood of its being found, or as to its significance if found. During the past three years I have examined in this way upwards of 60 men who suffered gunshot wounds of the chest during the war. They were referred to me by the Pensions Medical Board, in most cases because some of their symptoms or signs were suggestive of pulmonary tuberculosis. Parisot² and others have pointed out how closely the symptoms may resemble those of phthisis. Dyspnoea on exertion, cough, hæmoptysis, and pains in the chest are very frequently complained of; the toxic symptoms of active tubercle, such as tachycardia, sweats, anorexia, and headaches are, however, usually lacking. The signs and X ray shadows are often very puzzling, and in some cases only repeated negative sputum examinations will serve to exclude tubercle.

Sixty-five cases of old chest wounds have been examined. They may be divided into four groups: 1. Non-penetrating, where there was no evidence of injury to the lung at the time of wounding, 3 cases; these have no further interest. 2. Perforating—i.e., "through-and-through" wounds—15 cases. 3. Penetrating wounds, where the foreign body had been removed by operation either soon after the wound or later, 19 cases. In most cases the foreign body had been removed from the pleura or the chest wall, only in a few instances from the lung itself. 4. Penetrating, with foreign body retained, 28 cases.

The findings as to "band dullness" in the last three groups are shown in Table I.

TABLE I.

Group.	—	Cases.	Band dullness—	
			Present.	Absent.
2	Perforating	15	3	12
3	Penetrating—F.B. removed	19	3	16
4	Penetrating—F.B. retained	28	24	4

Two of the three cases in Group 2 with band dullness present had some degree of nasal obstruction.

With few exceptions the cases in Group 4 had been X rayed, but in most of them there was no exact localisation of the foreign body. In the four cases where band dullness was absent, and in three where it was present, the retained projectiles were probably outside the lung.

Two cases in Group 4 were definitely shown to be tuberculous by the finding of tubercle bacilli in the sputum. The remainder were considered non-tuberculous. This small proportion (3·2 per cent.) is in agreement with the general experience that chest wounds are comparatively seldom followed by phthisis.³ In view of the interest of the subject a brief note may be given of these two cases.

CASE 1.—Private, wounded in May, 1915, in second right interspace, piece of shell retained in upper lobe of right lung. In October, 1919, complained of sharp pain in right breast and shoulder, dry cough, and dyspnoea on slight exertion, and said that these symptoms had been present more or less since the wound. Pronounced dullness, feeble breath sounds, and impaired mobility of right upper lobe. Sputum: T.B. present. Was well and working 12 months later.

CASE 2.—Rifleman, wounded in 1915 in right lung, piece of metal retained in right upper lobe. He became fit again for service and was twice subsequently wounded in the limbs, and discharged from the army in December, 1918. In April, 1920, he complained of dry cough, pricking pain in right breast, and shortness of breath on exertion. Early signs of phthisis were found at right apex, and T.B. appeared in the sputum after the administration of iodide. The disease ran a progressive course, and the patient died in May, 1921.

It will be noticed that in both cases there is a long interval between the date of the wound and the discovery of active tubercle, so that the causal relation-

¹ C. Riviere: THE LANCET, 1915, ii., 387.

² J. Parisot: Rev. méd. de l'Est., June, 1921.

³ J. B. McDougall: Tubercle, 1920, i., 353.

ship must remain in doubt, but it is impossible to be sure how long symptoms of phthisis had been developing, and it is at least significant that in both cases the disease first appeared in that pulmonary lobe which contained the piece of shell.

Turning to the non-tuberculous cases, it appears from the table above that the presence or absence of the band dullness sign is closely related to the presence or absence of a retained foreign body in the chest. In wound cases, therefore, this sign cannot be taken as diagnostic of active tubercle. Accepting Riviere's view that the sign indicates an irritation or inflammation of the lung parenchyma, it appears that a bullet or shell fragment is not always retained by the lung with such complete indifference as has been thought. The cases described by Moynihan¹ point to the same conclusion. It appears also, since band dullness was found in some instances so long as seven years after the wound, that the symptoms due to a retained foreign body may last a long time, and are by no means entirely subjective. In two cases there was clear evidence from successive radiograms that the foreign body was changing its position in the lung. One of these patients had considerable hæmoptyses about the times of shift in position.

Symptoms of Old Chest Wounds.

The fact that a man is being examined with a view to reassessment of pension may very naturally enhance to some extent his description of his symptoms. Table II. shows the chief symptoms in the three groups.

TABLE II.

Group.	—	Cases.	Number complaining of—			
			Pain.	Dyspnœa.	Cough.	Hæmo- ptysis.
2	Perforating—	15	10	14	8	2
3	Penetrating—					
	F.B. removed	19	11	12	8	6
4	Penetrating—					
	F.B. retained	28	24	21	14	6
	Totals ..	62	45	47	30	14

The chief points to be noticed are the frequent complaint of dyspnœa and the comparative rarity of hæmoptysis in all the groups; and the relative frequency of pain, which might be expected, among the cases with a retained foreign body. These points are brought out more clearly in Table III., which shows the main symptom volunteered by the patient.

TABLE III.

Group.	—	Cases.	Number giving as main symptom—			
			Pain.	Dyspnœa.	Cough.	Hæmo- ptysis.
2	Perforating—	15	4	10	1	0
3	Penetrating—					
	F.B. removed	19	6	9	1	3
4	Penetrating—					
	F.B. retained	28	17	6	4	1

It will be seen that shortness of breath was a more prominent symptom among the cases free from retained foreign bodies, and that pain was much more conspicuous among those with a retained projectile.

The lung parenchyma is not sensitive to pain, so that this symptom is thought to be due to drag and pull on localised adhesions, where "a part only of the lung is firmly anchored to the pleura, the rest being free to move. A general diffuse adhesion between the pleural surfaces is not attended with pain, and, indeed, may be a means of preventing it" (Grey Turner, quoted by Moynihan). A missile which has passed through the chest wall in one place, and then lodged in the lung, is more likely to cause such a localised adhesion; but a missile which passes right through would be likely to cause at the wound of exit another adhesion tending to prevent this drag on one part of the pleura.

¹ Sir B. Moynihan: British Journal of Surgery, 1920, vii., 444.

Conclusions.

1. Wounds of the lung are only rarely followed by tuberculosis; two instances out of 65 cases were found in this series.

2. The physical sign of "reflex band dullness" is frequently found in old lung wound cases, when there is a retained foreign body.

3. Both this sign and the symptoms experienced by these patients suggest that a piece of metal retained in the lung keeps up a certain amount of chronic irritation.

A NOTE ON THE INTRAVENOUS INJECTION OF SERUM.

By POUL IVERSEN, M.D.

(From Blegdams Hospital, Copenhagen,
Prof. V. BIE, M.D.)

THE object of the serum therapy of diphtheria is partly to neutralise the toxin by degrees as it is absorbed and partly to neutralise the toxin already fixed by the tissues. The first requires that a certain presumably small concentration of antitoxin shall be present in the blood at the earliest possible moment; the second probably requires as high a concentration as possible. The object of treatment ought, therefore, to be to furnish the patient as quickly as possible with a high antitoxin concentration in the blood, and this is most easily attained by injecting the antitoxin serum intravenously. Objections can hardly be made theoretically against this method of procedure, as it has been shown that antitoxin which gets into the blood by this method disappears just as slowly as when it is injected subcutaneously or intramuscularly (Th. Madsen), but two practical points might deter doctors from employing the intravenous method as the principal treatment. Is the technique too difficult and the intravenous injection of serum dangerous? The technique should not be any hindrance, as it only consists in drawing up serum into a syringe under aseptic conditions and injecting it slowly into an arm vein. Experience alone can indicate any dangers arising from this method. I will therefore give an account of how the patients who were treated in Blegdams Hospital by intravenous injection in 1919, 1920, 1921, and the first half of 1922 have stood it, and how patients who had previously had serum tolerated reinjection, especially when it was given intravenously.

Description of Sera.

The serum is supplied by the Danish State Serum Institute. It has mostly contained 0.5 per cent. phenol, 400 units per c.cm. During the last year 1.0 per cent. chinisol has been added in place of phenol. At one time the serum was concentrated by fractional precipitation with ammonium sulphate. Quite recently the Serum Institute has succeeded in raising the antitoxin in the horse's serum as high as 800 units per c.cm. without precipitation or concentration in any other way. This strong native serum and chinisol serum represent a considerable advance. As regards cases of serum disease we have not observed any difference between these sera.

First Injections.

Altogether 406 patients, who had not previously had serum, received intravenous injections. Of these 27—that is to say 7 per cent.—presented the first couple of hours after the injection an affection only rarely seen after intramuscular injections, which usually takes the form of a rigor of 10–30 minutes' duration. The pulse is small and the patient blanched. More rarely the rigor is absent and the attack resembles a mild collapse. With the exception of a single case, where the patient was confused and sluggish for a couple of hours, the condition is quite transitory and easily counteracted by subcutaneous injection of camphorated oil. A serum rash appeared in 54 per cent. of the patients between the fourth and fourteenth day, the average day being the ninth.

Classification of Cases.

The cases are classified according to the different years.

In 1919 68 injections were given. After nine of the injections (13 per cent.) the above-mentioned attacks occurred, rigors six times and collapse three times. In all nine cases 20 c.cm., containing 8000 units, were injected. An 8-year old girl received 45 c.cm. serum and a 10-year old girl 30 c.cm. serum without disagreeable after-effects.

In 1920 119 injections were given. After one of the injections only was there a slight attack of collapse, with no rigors. In this case 24,000 units were given intramuscularly on admission. On the next day 44,000 units were given intramuscularly + 4000 units (10 c.cm.) intravenously. Half an hour after the intravenous injection there was a tendency to collapse.

In 1921 174 injections were given. After ten of the injections (6 per cent.) rigors occurred eight times and collapse twice: 10-40 c.cm. serum were given, containing 8000-32,000 units.

In 1922 (first half year) 45 injections were given. After seven of the injections (15 per cent.) rigors occurred five times, collapse once, associated with a serum rash immediately after the injection, and once an attack of giddiness: 10-20 c.cm. serum were given containing 8000-16,000 units.

In elaborating the material I have been unable to help noticing that the attacks are independent of the size of the serum dose, and that their number varies greatly from year to year. These facts indicate both individual idiosyncrasies and differences in the serum used.

Reinjections.

I will now proceed to discuss reinjections, concerning which we have at the beginning been chary, on account of the anaphylactic shock manifested in animal experiments. Reinjection was carried out from January, 1916, to July, 1922, in 99 cases, from a few months to about 15 years after the first injection. In some cases we tried to desensitise by giving 1000 units subcutaneously 5 to 24 hours before the therapeutic injection, in others (a very few) by injecting 1 to 2 c.cm. serum intravenously in the course of ten minutes. In both methods the interaction between certain protein substances, which takes place after the injection, should occur so slowly that shock is avoided. In the majority of cases, however, we have either injected the usual serum dose intravenously, but very slowly to begin with (10-20 c.cm. in the course of 20 minutes) and at the same time given an intramuscular injection, or we have injected the whole amount intramuscularly.

In 18 out of the 99 cases desensitisation was attempted by subcutaneous injection, but the diphtheria disappeared so quickly in 9 of them that the subsequent injection was omitted. In none of these 9 cases was any serum disease observed beyond some reaction at the point of inoculation. In the other 9 cases an intramuscular or a single intravenous injection was given later, usually on the day after the subcutaneous injection. In 6 of these 9 cases nothing happened. In 1 case a slight rigor occurred four hours after the subcutaneous injection, but nothing occurred the day after, when 12,000 units were injected intramuscularly; in 1 case there was a rigor two hours after an intramuscular injection of 40,000 units. This patient developed an enormous serum rash on the fifth to sixth day, and also a small soft pulse. The patient who received an intravenous injection had severe vomiting after the injection (28,000 units).

In 18 cases an intravenous and an intramuscular injection were given without the desensitisation procedure. The intravenous injection was given slowly in the course of 10-20 minutes. In 13 cases nothing happened: in 2 cases while the intravenous injection was taking place,* and in 2 cases, 1-1½ hours after the latter, the patients had a rigor of the same kind and severity as those observed in patients who had not previously received serum. In the last case (diphtheria gravis) 10 c.cm. of serum was given intravenously without unpleasant results, but ten minutes after 100,000 units were injected intramuscularly, in immediate response

to intravenous injection, the patient collapsed. The pulse was somewhat improved by a stimulant, but the patient died four hours later. This patient, who was admitted on the fourth day of the disease, was moribund when taken into hospital; death was, therefore, not due to the serum injection. In 63 cases 10-80 c.cm. serum were injected intramuscularly, also without preliminary desensitisation. In 57 cases nothing happened; once there was a little collapse, and three times there was an urticarial serum rash shortly after injection. In 2 cases in which a very intense serum rash appeared on the fourth and fifth days respectively, collapse occurred simultaneously with a very small or imperceptible pulse, which, however, was much improved by a subcutaneous injection of camphorated oil. The first of these cases is reported in detail later on.

These two cases, as well as the last one mentioned in the group which had first received a subcutaneous serum injection, undoubtedly exhibit the most unpleasant symptoms for patient and doctor. The patient is very distressed by the itching rash, oedema of the face, particularly the lips, and pains in the joints. The doctor is perturbed by the bad pulse which may occur periodically. In patients who have not previously received serum a similar morbid picture may occur, but scarcely with such severity as in these three cases, the clinical notes of one of which will be given.

CASE 145.—Female, aged 11 (1918). Membrane covers the tonsils. The patient was admitted on Jan. 9th, and received 20,000 units of antitoxin intramuscularly. On the 10th she slept well, membrane decreasing. On the 11th remaining membrane small. On the 12th small spot on uvula. On the 13th, 5 A.M., patient became blanched, with cyanosis of the lips, moist with sweating, cold, relaxed, with a small quick pulse, and nausea. This attack lasted about two minutes. Simultaneously an urticarial serum rash broke out on the cheeks, which itched. There was considerable oedematous swelling of the lips (negro lips). In the space of a quarter of an hour the eruption had spread over the whole face with the exception of the lips and chin, and also appeared in small spots on the arms and legs. Nothing at the site of injection. In the course of a couple of hours the eruption also increased in extent on the extremities, but remained unchanged on the face. After six hours it had almost disappeared. At this time (11 o'clock) she felt well and had a good appetite. At 7 o'clock and 8 o'clock there had been attacks of nausea, but otherwise no symptoms of collapse. On the 14th the patient was feeling well; pulse 68, regular, strong; condition of heart normal; edge of liver at costal margin. On the 16th, 17th, and 20th nausea and serum rash were again noted, with no serious symptoms of collapse.

This case was unpleasant enough, but the dangerous condition of collapse was quickly over. In other cases it recurs and they have a more protracted course. The injection of camphor seems to be a good remedy in combating the collapse. From the cases of reinjection referred to it appears that there is no advantage in desensitising by giving 1000 units subcutaneously, and as this directly hinders the necessity of immediately providing the blood with an adequate amount of antitoxin, we ought hardly to employ this desensitising method in cases which we know for certain will require a large injection later.

That the three unpleasant attacks of serum disease cited all occurred in patient who had received an intramuscular injection, is hardly more than chance; the intramuscular injections were more than four times as numerous as the intravenous injections. If we except the case of diphtheria gravis which led to death some hours after admission, there were four rigors in 17 intravenous injections—that is, about 24 per cent. of the cases. None of the cases were dangerous.

Leaving aside the 9 cases where only 1000 units were given subcutaneously, 74 per cent. got a serum rash on the first to tenth day, usually on the sixth day. Complete information concerning the attacks of serum disease in these patients after the first serum injection cannot be given.

A special little group of 21 patients, with a single exception (a week), have again received serum four to eight weeks after the first injection, usually

* The injection was stopped as soon as the rigor occurred.

40-50 c.cm. (16,000-20,000 units) intramuscularly two days in succession, in order, if possible, to have a favourable effect on the paralysis. From the therapeutic standpoint the result was negative. It is, however, of interest to see how these patients react to a serum injection at a time when we should expect them to be particularly sensitive. In four patients desensitisation was carried out by means of 1000-2000 units subcutaneously five to six hours before the real serum injection. In one of these, and in three of the other 17 patients, there was some vomiting. Apart from some reaction at the point of injection 14—that is, 66 per cent. of all the 21 cases—developed a serum rash on the first to fifth day, *usually on the second day*. In no case were dangerous symptoms seen.

Summary.

The intravenous injection of diphtheria antitoxin is not a dangerous method. It should be the method of choice, even in patients who have previously received serum. It is only necessary to give the injection slowly, and temporarily or definitely discontinue it on the appearance of any reaction on the patient's side. The material relating to the intravenous re-injection, however, comprises only 19 cases. The most unfavourable attacks after re-injection occur at the time when the serum rash appears.

THE TOXÆMIC ASPECT OF OCULAR DISEASE.

By PERCY DUNN, F.R.C.S. ENG.,

CONSULTING OPHTHALMIC SURGEON, WEST LONDON HOSPITAL;
LATE LECTURER ON OPHTHALMOLOGY, WEST
LONDON POST-GRADUATE COLLEGE.

A TOXIC condition of the blood affects in varying degree the nutrition of the eye. Eight years ago, in a paper contributed to THE LANCET,¹ I dealt with this subject under the heading of "Some Aspects of the Ciliary Body in Health and Disease." In effect the object of the paper was to draw attention to the numerous cases of hypothyroidism met with in ophthalmic practice.

Diagnostic Signs.

Thyroid insufficiency may be translated into failure of the thyroid to protect the body against some source of toxæmia. In such cases the gland becomes unequal to the demand made upon its functional activity, and its failure is manifested by numerous signs. It has been the habit in ophthalmic practice to overlook these signs; to treat the patients on general, because orthodox, principles; to ignore the hypothyroid condition and the significance of its presence; to disregard the obvious fact that behind the thyroid insufficiency there must be a cause into which inquiry should be made. It has been the custom, when a toxæmic condition is supposed to account for an irido-cyclitis, to inquire only into some recognised focus of septic infection, as, for example, the mouth. The possibility that the eye can exhibit infective changes arising from another source of toxæmia, in the course of which marked hypothyroidism is manifest, has received but little attention. The fact, however, is that the ciliary body—the "blood" organ of the eye—is peculiarly responsive to the effects of toxæmic foci. A notable example of this is the chronic irido-cyclitis known under the name of K.P. This is a disease often of prolonged duration, fluctuating always between improvement and relapse, and proverbially showing a disposition to resist the ordinary methods of orthodox treatment resorted to for its relief. Its notorious intractability to treatment is the measure of the failure to deal with its toxæmic source, the existence of which is proved by the signs of thyroid insufficiency

present, and the favourable influence upon the course of the disease which thyroid treatment ensures. Closely allied to the symptoms characterising K.P. are those accompanying interstitial keratitis in children. Such children are regarded as the subjects of congenital syphilis.

But how often does it happen that we are unable to find any evidence elsewhere confirmatory of an active syphilitic taint. Even if a syphilitic origin of the disease be admitted, parenchymatous keratitis cannot be held to be a manifestation of a syphilitic process in activity. Were this to be so, on the contrary, anti-syphilitic treatment, which is so commonly resorted to, could scarcely fail to check the course of the disease. General experience, however, has determined that this method of treatment has no influence in controlling the active inflammation present. Moreover, apart from the ocular signs, the small patients are generally (invariably it may be said) the dejected objects of advanced malnutrition and marked anaemia. Again, they exhibit many signs characteristic of hypothyroidism. Finally, the keratitis is secondary to an acute cyclitis, such as might be expected to follow the physical conditions present. That parenchymatous keratitis in children is mainly a toxæmic manifestation is supported by the treatment which I came to adopt for its relief. The children were kept in bed, fed up on a generous diet, and 3 gr. of thyroid gland were given twice daily. As the physical condition improved so the intense photophobia and the keratitis subsided. Atropine, with fomentations, was the only local treatment necessary. Thus the toxæmia was held in check by the thyroid administration, and gradually normal nutrition came to be re-established.

"Sympathetic Ophthalmia."

There is another disease of the uveal tract, especially destructive in its effects, suggestive also of being associated with a general toxæmia. The aetiology of the irido-plastic cyclitis, known under the popular unscientific name of "sympathetic ophthalmia," still remains a myth. Theories abound as to its origin; nevertheless the problem is no nearer solution than was the case in ancient times. Our forefathers, greatly puzzled by the destructive incidence of the disease, willingly enough no doubt, accepted the hypothesis that "sympathy" could be a cause of inflammation. Custom has led to this interpretation being retained. Ophthalmic surgery still continues to be adorned by this particular terminology, which is conceded to be a solecism, but which at the same time is a reflection upon the science of our age. The possibility that the disease may be of toxæmic origin has hitherto escaped observation. Although every attempt has so far failed to isolate an organism as the causal agent, it may so be that there is one of a saprophytic type which only becomes virulent when exposed to a toxic environment. The colon bacillus is normally a saprophytic organism; in the intestines it exercises an inhibitory influence upon the putrefactive bacteria of the faeces. When, however, intestinal stasis is present, the putrefactive bacteria increase, the colon bacillus becomes pathogenic, and completes the vicious circle of the pervading toxæmia. The inference is reasonable that were an organism such as we have supposed in an injured eye to become pathogenic owing to this toxæmia its special toxin might be productive of the acute irido-plastic cyclitis in the wounded organ, to be followed subsequently, in the absence of due prophylactic measures, by the involvement of the sound one. The vulnerability of the ciliary body to toxic infection is sufficient to imperil the recovery of an eye, either after injury or following an intra-ocular operation. Plastic irido-cyclitis has developed even after the strictest antiseptic precautions practised in the course of an operation. The peril of the disease is by these precautions not averted. Natural repair of the tissues cannot be expected with blood infected with toxic products.

¹ THE LANCET, 1915, i., 1129.

Intestinal Disinfection.

All this, of course, may be regarded as pure hypothesis. Nevertheless it bears closely upon the theme which has been of late impressed upon me, and which it is the main object of this paper to emphasise—namely, the importance of the relationship of intestinal toxæmia to ocular disease. What, again, are the facts? Hypothyroidism associated with disease changes is proof of a pervading toxæmia. The toxæmia is subject to control by thyroid therapy, more or less. But in the case of the toxæmia arising from intestinal stasis the most scientific method of treatment must obviously be the sterilisation of the putrefactive organisms in the intestines.

By the introduction of the new benzene derivative dimethylmethoxyphenol, the putrefactive organisms are destroyed and the *B. coli*, owing to their "greater powers of resistance,"² under the changed environment are enabled to cast off their pathogenic virulence and resume their normal character. The significance of this addition to our therapeutic resources suggests the beginning of a new era in the treatment of disease; the fact that the poison trap of the intestines can now be brought under control may prove to be the solution of more than one hitherto undetermined pathological eye problem.

And not in man only will this advance prove to be effective. Animals also are subject to intestinal toxæmia. Calves, for example, are the subject of a disease known as "white scour." This apparently corresponds with the summer diarrhoea of children, and is attended with similar fatality. Sterilisation of the intestines of the affected calves has been found to arrest the disease, and recovery has followed. Some fascination undeniably belongs to the contemplation of the numerous problems of disease regarded from the aspect of intestinal toxæmia and its new treatment, and the study of this subject gives promise of yielding valuable clinical results.

A NOTE ON

GLUTEAL ANEURYSM AND RUPTURE
TREATED BY ANTILLUS'S
OPERATION.

By A. WILFRID ADAMS, M.S. LOND., F.R.C.S. ENG.,

HONORARY ASSISTANT SURGEON, BRISTOL ROYAL INFIRMARY;
SURGEON WITH CHARGE OF OUT-PATIENTS, BRISTOL
HOSPITAL FOR CHILDREN.

THE following case is of sufficient interest to merit record.

A soldier, aged 30, was wounded in the left buttock by German shrapnel in 1918. Next day an embedded missile was removed and the wound healed well, leaving no disability. I saw him in the out-patient department, Bristol Royal Infirmary, on Dec. 5th, 1921. On leaving his office two days before, and taking a few steps, he felt a tearing sensation in his left buttock; his leg gave way under him, "the use going out of it," and he fell, but managed to rise and limp home.

Condition on Examination.—He looked pale and ill, though his mind was alert. Temperature 100° F. Pulse 100. When standing he supported himself by means of a stick. He had to lie on his side on the couch owing to the pain in the buttock. On turning him into the fully prone position a low-domed swelling was found at the painful site. The skin appeared healthy, save for a healed superficial oval scar 1½ inches long situated about the middle of the buttock. The swelling was very tender, smooth, and compressible, as far as could be tested. It had an expansile impulse corresponding to the radial beat and seemed to underlie the gluteal muscles. The pulsation, most marked centrally, extended from the iliac brim downwards over an area about 8 inches in diameter. A systolic bruit was audible over it and more faintly in the left iliac fossa. The pulse in the posterior tibial arteries was equal. The abdomen and rectum felt healthy. There was little loss of movement in the limb, and no evidence of nerve pressure. X rays showed no bony lesion or shrapnel. Syphilis was denied.

² THE LANCET, 1921, i., 758.

Subsequent Course.—Leaking traumatic aneurysm was diagnosed, and he was admitted as an in-patient under the care of Mr. T. Carwardine. The same night pain in his buttock woke him. This was still present on Dec. 7th, but no evidence of paralysis of the sciatic nerve appeared. The pain and other signs in the swelling did not subside, and immediate operation was planned.

First Operation.—On Dec. 7th, transperitoneal ligation of left internal iliac artery. A median laparotomy was performed, the Trendelenburg position being adopted. The left internal iliac artery was easily located and a marked thrill felt in it which was absent on the right side. The gluteal swelling became smaller, losing its pulsation as the artery was ligated. On the 16th the swelling enlarged and became pulsatile again. This was thought to be due either to premature absorption of catgut ligature, or the opening up of the circulation across the pelvis from the branches of the opposite internal iliac artery.

Second Operation.—On the 12th, transperitoneal ligation of the gluteal and obturator arteries. The former incision was reopened, and the ligature on the internal iliac artery was found safely in situ. There was, however, faint pulsation in the gluteal artery, so this vessel and the obturator were ligated. All pulsation left the buttock swelling, but in the ward three hours later it was again felt and did not diminish. Ligation having proved unsuccessful, Antyllus's operation was planned.

Third Operation.—On the 30th, whilst an assistant made direct digital pressure on the abdominal aorta as required, through an opening in the upper end of the former incision a direct attack was made upon the aneurysm. A cutaneous flap was turned down over the swelling in the left buttock, and a 4-inch muscle-splitting opening made through the gluteus maximus. A bluish feebly-pulsating swelling was displayed, about the size of a hen's egg, and was partly freed from the surrounding structures. Whilst the assistant compressed the abdominal aorta the sac was incised and a rush of blood took place. Hæmorrhage was controlled by a large swab on the aneurysmal bed, and as this swab was gradually unrolled the mouths of afferent vessels were seized with forceps. The neck of the sac, which was in contact with the upper margin of the great sciatic notch, was tied off with No. 6 thread. Gauze packing and a tube were inserted as a temporary measure, and the wound was closed.

Recovery was rapid but not complete. The patient returned to work on March 1st, 1922, but suffered from pain, in the buttock and limbs. He died suddenly on July 23rd from symptoms suggesting pulmonary embolism.

Remarks.

In this case a diagnosis of sarcoma or abscess was partly excluded by the history of sudden onset. The patient successfully underwent three major operations within 23 days. The failures of the first (Hunterian) operation and the second, which was equivalent to Anel's operation, are instructive, as in both instances pulsation was temporarily arrested. A similar experience is recorded by Gillette,¹ where pulsation recurred in a gluteal aneurysm seven months after apparently successful ligation of the internal iliac artery. My conclusion is that aneurysm of the gluteal artery should be treated by:—

1. Preliminary ligation of the internal iliac. This is in itself harmless and will control hæmorrhage from sac.

2. The aneurysmal sac is dealt with locally according to the condition found in the buttock: (a) if the wall of the sac is ill-defined, as in this case of ruptured aneurysm, intra-saccular ligation is best; (b) if a well-formed sac is present, then obliterative endo-aneurysmorrhaphy is the ideal method.

DONATIONS AND BEQUESTS.—The Right Hon. T. R. Ferens, High Steward of Hull, has given £2000 to the Hull Royal Infirmary to enable better equipment to be acquired for dealing with cancer.—The governors of the Oldham Royal Infirmary have received £2000 from Mrs. Elizabeth Shorrocks, Hollinwood, to endow two beds, one in memory of her husband and the other in memory of her daughter.—Mr. Munro Page, of Huddersfield, left £150 to the Huddersfield Royal Infirmary and £100 to the Huddersfield Deaf and Dumb Society.—Mr. Richard Ward, of Kirkham, Lancashire, left £1000 to the Preston Royal Infirmary and £500 to St. Dunstan's Hostel for the Blind.

Medical Societies.

CHELSEA CLINICAL SOCIETY.

THE annual debate of this Society was held in the Club Room of St. George's Hospital Medical School on March 20th. In the absence of the President, Dr. T. B. HYSLOP was in the chair.

Sir CHARLTON BRISCOE introduced the debate on VISCEROPTOSIS.

He said that recently he had been interested in the study of the mechanics of respiration, and particularly of the diaphragm which was generally accused of being the prime factor in the production of visceroptosis. The act of respiration was carried on by two distinct mechanisms, thoracic movements and diaphragmatic movements. Generally both were concerned in respiration, but in the majority of individuals one type of respiration predominated—either the thoracic or the diaphragmatic. The thoracic breather, the rarer type, was apt to develop the type of chest known as emphysematous with a wide subcostal angle, although this was not necessarily associated with emphysema. In these persons the abdominal muscles were quite lax. In abdominal breathing the descent of the diaphragm was associated with contraction of the external and internal oblique and the transversalis. These muscles were most strongly developed in the flanks and in the epigastrium, above the level of the tenth ribs. It was the part below the level of the tenth ribs and internal to the anterior iliac spine, controlled by the weaker parts of these muscles which yielded. The rectus was not a muscle of respiration and played little part. This was the type in which visceroptosis might be expected to occur; and the commonly seen visceroptotic subject was a female with a small lower thorax and acute subcostal angle in whom there had been a loss of fat, while pregnancy or prolonged illness produced yielding of the lower abdomen. The speaker believed that the visceroptotic habit was produced early in life; while all new-born infants had very much the same type of chest, the two types began to be differentiated about three to five years of age. Curvature of the back from bending over unsuitable desks at school, fatigue and over-exercise, myopia, nasal obstruction from adenoids and constant colds, and increased intra-abdominal tension were all aetiological factors in producing abdominal respiration and the visceroptotic habit. Lack of proper exercise to develop the upper chest also favoured abdominal respiration. Since the habit was found early in life, prevention should begin at an early age by eliminating the factors the speaker had already enumerated.

Discussion.

Mr. IVOR BACK was inclined to question whether visceroptosis existed as a clinical or pathological entity. Impressions of human anatomy and particularly of the position of the abdominal viscera had been gathered, in the past, from the formalin-hardened dissecting-room specimen. We now knew that in the erect attitude the abdominal viscera did not occupy any such position as that seen in the dissecting-room—the opaque meal and X rays frequently demonstrated a cæcum in the pelvis and a transverse colon resting on the pubes, positions which he was now inclined to regard as quite normal for many individuals. Ptosis of the kidney was recognisable by palpation without X rays and at one time was blamed for many vague abdominal symptoms, and various types of nephropexy were extensively practised on this account. This operation was now rightly discredited unless the symptoms, such as Dietl's crisis, definitely incriminated the ptosed kidney. Indeed, in recording the results of this operation in 448 cases the surgeon himself could only claim 55 per cent. of cures one year after (a very poor result for a modern operation), while 26 per cent.

were "no better or worse." The visceroptotic patient was generally a thin woman and a potential neurasthenic, often with domestic worries. To tell this woman that the X ray examination revealed a dropped intestine was to convert a potential into an actual neurasthenic. The usual sequence was that after a trial of an abdominal belt the patient went to a surgeon who advised and performed various pexy operations with results that were often brilliant for six months or a year, in fact, until the suggestion that operation would be curative had passed off, after which the patient returned to her former state. He thought there must be something wrong with an operation, the results of which were explained by its advocates in two entirely different ways, by some on a mechanical basis and by others as relieving the drag on the mesenteric nerves. He pleaded for the same sanity as regards colopexies as now held in the case of nephropexy. In a few cases he thought patients with chronic constipation and a large blue, boggy cæcum constantly in the pelvis derived some benefit from fixing the cæcum, but that organ must not be deprived of its natural mobility.

Dr. ROBERT HUTCHISON believed that visceroptosis was a definite clinical entity of great interest, but very difficult to diagnose both from its almost constant association with neurasthenia and from the fact that it was a great imitator of acute organic abdominal lesions. He could not agree entirely with Sir Charlton Briscoe as to its aetiology, since diaphragmatic breathing was less common in women who were usually the subjects of the disease. He attached more importance to the size of the pelvis in women and the derangements of its floor in consequence of pregnancy, and to loss of the supporting fat within the abdomen, but was inclined to agree that the muscular hypotonus which led to visceroptosis was the result of an inborn diathesis. Visceroptosis might be present without any symptoms; but the ptosed viscera acted at a disadvantage, and symptoms were produced if there was atony of the visceral muscle, or of the abdominal muscle leading to decreased intra-abdominal tension. He thought that the dependent position of the viscera led to the pooling of blood in the abdomen and consequent venous congestion. The diagnosis of visceroptosis as the cause of symptoms often presented the utmost difficulty. He had seen cases clinically resembling gall-stones or gastric ulcer where operation revealed no lesion other than visceroptosis, and thought that operation was demanded in these cases for diagnostic purposes, since there was no other means of finding out whether there was or was not a true acute abdominal lesion. He understood that nephropexy had been given up 15 years ago, and maintained that the utmost caution should be observed in advising surgical treatment apart from exploratory operation. Medical treatment was complicated by the mental symptoms, but something could and should be done for the various pains and draggings which, however slight their pathological basis, were very real to the patient. It was very important that medical treatment should begin early, and especially before the patient had submitted to multiple abdominal operations. The indications were to build up the abdominal wall and to repack the abdomen with fat. Many patients experienced relief from wearing a belt, not because it held up the viscera (for it did not), but on account of the increased intra-abdominal tension it produced. If the atony of the gut could be dealt with patients would be able to overcome the mechanical disadvantage of the ptosed intestine, and any method of sustaining the pelvic floor would be helpful.

Mr. MORTIMER WOOLF had always regarded visceroptosis as the result of a congenital defect. In the cases he had seen in the post-mortem room, the operating theatre, or the dissecting room the ascending colon had a mesentery while the normal mesenteries were unusually long. This was not due to mere stretching, since the mesentery was often fat and vascular, but, he thought, to failure of the normal

fusing of the right leaf of the mesentery with the posterior abdominal wall. As the result of reading Mr. Waugh's paper he had begun to investigate the frequency of visceroptosis and was surprised to find that marked ptosis of the hepatic flexure existed in many cases very often without any symptoms. He had operated on a few cases with symptoms but the results had not been satisfactory, so that he would no longer operate except for intercurrent disease. Nephropexy he only performed when the presence of such symptoms as Dietl's crisis definitely incriminated the ptosed kidney. He thought that the low position of the colon as seen radiographically might very well be due to the weight of metal in the gut, and further, that the hepatic flexure was not normally fixed either in position in the body or as regards the portion of the colon forming the actual flexure. Mr. Woolf emphasised the importance of not attributing all abdominal symptoms to visceroptosis, and of bearing in mind superadded conditions, such as bands and chronic appendicitis. He quoted a case in which right-sided abdominal pain associated with very marked visceroptosis in a young woman was found at operation to be due to gall-stones and chronic appendicitis. Finally, if a belt were worn for this condition it was essential that it should not be allowed to ride up to the upper abdomen, and for this purpose it should be provided with perineal bands.

Adjourned Discussion.

The discussion was resumed on March 27th, with Dr. J. CAMPBELL McCURE, the President, in the chair, when Dr. F. HERNAMAN-JOHNSON spoke of visceroptosis in the anatomical sense. Two types, he said, were recognised. The first commonly followed pregnancy, when the viscera were ptosed owing to the laxness of the abdominal wall: the viscera could in these cases be made to regain a normal level by treatment. A belt was required by some of these cases as a temporary expedient; other cases required electrical stimulation of the abdominal muscles. If all women received proper treatment of the lax abdominal wall after parturition there would be fewer cases of visceroptosis, prolapse, &c., for these were often preventable by early and suitable treatment. The second type, in which visceroptosis was congenital, occurred in tall thin "slab-like" women, often very energetic. When X rayed the viscera were found to be low, but the condition was not incompatible with perfect health. When symptoms occurred they often simulated appendicitis, and were due, he thought, to response of the abdominal sympathetic to stimuli which normally would have no action. In these cases again electrical stimulation of the muscle was beneficial, although it was difficult to explain why it should be so. The presence of an adhesion (the diagnosis of which by X rays might be fallacious unless great caution were observed), a cæcum in the pelvis combined with stasis for 24 hours, and the failure of medical treatment after a fair trial, all called for surgical treatment, which in these cases was attended with good results.

The PRESIDENT remarked on the frequency with which anatomical visceroptosis was present without symptoms, and while agreeing that many subjects of visceroptosis conformed to the thin type described by previous speakers, he pointed out that some were of fat and muscular habit. The work of Keith in this country and Cannon in America showed that while the general tone of the hollow viscera was controlled by the vagus the physiological sphincters at the cardia, pylorus, ileo-cæcal valve, &c., were under the control of the sympathetic. It was the lack of balance between these two opposing innervations which caused the symptoms when these were present. In a paper entitled "Neurasthenia Gastrica" (THE LANCET, 1915, ii., 695) he had pointed out that the vagoasthenic type gave way under the influence of overstimulation of the sympathetic from mental worry. Long-continued irritation, as from chronic appendicitis, or even in children from phimosis, acted similarly in causing loss of tone in the stomach and colon. The

visceroptotic whose symptoms were cured exhibited no change in the position of the viscera: what had happened was that he had regained the normal balance between vagus and sympathetic action in the viscera. It was in fact not a question of the position of the organs, but a question of the presence or absence of gastro-intestinal stasis. At Guy's Hospital they found that amongst their students the most pronounced ptosis existed in the best athlete. A hint of the possible endocrine origin of intestinal stasis was given by the discovery by Sir A. Keith¹ in the crypts of colons excised for stasis of a pigment allied to adrenalin. Further support was given to this theory of the cause of stasis by the fact that the administration of adrenalin aggravated the symptoms. Intestinal hypotonus and gastric hypochlorhydria were often associated, and the beneficial results of treatment of the latter might possibly be due to stimulation of the vagus. Another possible factor in the production of symptoms was the dilated duodenum (so often present in visceroptosis) where it was possible that toxic bodies were formed which depressed the vagus or stimulated the sympathetic.

Dr. BEAVER MENNELL said that the practice of physio-therapy was as yet empirical, for often there was no scientific basis for the treatment adopted, although in practice this was found to do good. Treatment of visceroptosis might be prophylactic or directed against the established condition. Many women came for treatment with the condition well established after pregnancy. There could be no doubt that the abdominal muscles played an important part in the control of the action of the viscera, and after pregnancy these muscles were weak and overstretched, and very often were deliberately allowed to remain so by the patient on account of the pain caused by their contraction. At St. Thomas's Hospital the electrical exercise of these muscles was now part of the routine treatment during the puerperium. In the chronic neurasthenic type of visceroptosis ordinary exercise which made further demands on the nervous system would not be tolerated, and recourse had to be made to electricity, using plain faradic stimulation, to exercise the muscles without causing nerve or heart fatigue. Massage, although never curative by itself, was helpful later. The Bergonié chair, which had been on the whole disappointing for the purpose for which it was designed—namely, for reducing weight—helped these visceroptotic patients much; whether the good effect was due to skin stimulation reflexly affecting the vagus or merely to abdominal massage, he was unable to say. For women with a low blood pressure and lax abdominal wall a belt was helpful, possibly by raising the intra-abdominal pressure and thus preventing the accumulation of blood in the splanchnic area. Since he had noticed that in many cases strain of the sacro-iliac joints was associated, possibly reflexly, with constipation, even in muscular individuals, he advocated that where a belt was fitted it should be so designed as to support those joints.

Dr. H. A. ELLIS, who had worked in this subject, partly in conjunction with the President and partly by himself, was convinced that the symptoms of visceroptosis when they occurred were due to atony of the gut. Cutaneous stimulation would cause the gut to contract, and different areas of the skin were associated in this manner with different parts of the gut. The visceroptotic was essentially an alkaline type with deficient gastric acidity. He had noticed in many of these cases the presence of an abnormal albumose in the urine, which he suggested might have an origin in the duodenum either from the absorption of albumose or from an error in fermentation. Some derangement of innervation was probably the prime cause of the condition.

Dr. D. M. BARCROFT thought that the disease was generally congenital and exhibited a tendency to appear in members of a family. In proof of this he described a family, three members of which had

¹ Discussion R.S.M.: The After-Results of Colectomy, THE LANCET, 1922, i., 636.

recently come under his care. The first sister had abdominal pain accompanied by unusually prolonged pyrexia, and X rays showed marked visceroptosis. Appendicectomy and fixation of the cæcum had relieved her. A second sister developed abdominal symptoms (pain, flatulence, &c.) while studying for a music examination, but recovered after the examination was over. A third sister, who returned hurriedly from Italy on account of the illness of the first, complained of pain in the right iliac fossa and had a dropped kidney. The mother had the scar of an operation for removal of the right kidney, which had been performed after nephropexy had failed. Two other members of the family were of similar type. He thought that the environment of these patients had a powerful effect in bringing on symptoms, and many cases would get better if the environment could be changed. The vague pain in the sacro-iliac joints referred to by some speakers as associated with the visceroptosis was difficult to treat.

Dr. J. F. HALLS DALLY said that our knowledge of the origin and treatment of visceroptosis had advanced but little since the time when Glénard first described the complex. He thought that when symptoms were present there was a condition of general hypotonia in other systems besides the abdomen, and notably in the circulatory system. The blood pressure was generally low, but occasionally it was high from associated intestinal toxæmia. Another antagonism which entered into the picture, besides that between the sympathetic and vagus, was the opposing effects of the diaphragm and abdominal muscles in respiration. He suggested that lumbosacral pain was due to actual dragging on mesenteries and that the cause of symptoms in visceroptosis was the intermittent discharge of depressor substances into the blood.

Sir CHARLTON BRISCOE replied briefly.

CARDIFF MEDICAL SOCIETY.

A CLINICAL meeting was held on March 13th, Prof. E. J. MACLEAN, the President, in the chair.

Gas, Oxygen, and Ether Apparatus.

Dr. H. GORDON GREAVES read a paper on the evolution of the methods for producing anaesthesia, in which he summarised the history of anaesthetics from the year 1776 when Priestly discovered nitrous oxide and also oxygen up till the present day. The contributions of Sir Humphry Davy in 1798, Henry Hickman in 1820, Horace Wells in 1844 were summarised, before the day of Frederic Hewitt was reached. Of Hewitt the speaker said: "To his great scientific and mechanical skill we owe many of the data which have enabled us to apply 'gas and oxygen' to everyday surgical use, as he went deeply into the methods of administration of (1) N_2O pure, (2) definite proportions of N_2O and air, (3) indefinite proportions of N_2O and air, (4) definite proportions of N_2O and O_2 , (5) varying proportions of N_2O and O_2 . In 1886 he devised his twin bags and special valves, with which he could give varying, but definite, proportions of gas and oxygen."

Through the following years, he continued, many apparatus have been evolved, but the war gave an enormous stimulus to anaesthetic and surgical procedures, and, in the speaker's opinion, the best present-day apparatus was that devised by Mr. Boyle, which he described.¹ The dangers of gas and oxygen Dr. Greaves considered few, and the great advantages as follows:—

1. Very ill and shocked patients recover quickly from its effects.
2. Feeble and septic patients do well because N_2O is non-toxic itself and does not increase the susceptibility of the body to the toxins set free from injured tissues.
3. Diabetic patients are less likely to go into a state of coma than with ether or chloroform.
4. Very long operations on not very sensitive parts can be undertaken with little risk of bad after-effects.
5. Obstetrical work is well done under gas and oxygen without risk to mother or child.

¹ THE LANCET, Nov. 3rd, 1917, and Feb. 8th, 1919.

6. Nausea and vomiting are much less likely to follow than after chloroform or ether.

7. Delayed forms of acidosis do not seem to occur.

Congenital Hydronephrosis.

Dr. IVOR J. DAVIES showed specimens from a case of small white kidney with an associated congenital hydronephrosis. The patient was an intelligent small girl of 15. The state of nutrition was poor, and a slight degree of anaemia was present. The complexion was sallow. Measles in childhood and a few attacks of tonsillitis in recent years were the only previous illnesses. There was no evidence of an antecedent nephritis. She was one of eight children, the others being healthy. The duration from the onset of symptoms to the termination was 15 months, the last three of which were spent in hospital. Severe paroxysmal headache was a feature from the onset, and was associated with occasional attacks of vomiting after meals, which became more frequent in the later stages, and during the last week the vomit contained altered blood. Puffiness under the eyes and swelling of the feet and ankles in the last few weeks were observed, otherwise there was an entire absence of cedema. There was much thickening of the peripheral arteries with a hard pulse. The systolic blood pressure only fell below 200 m.m. on a few occasions, and was generally a little higher. A slight degree of hypertrophy of the heart was evident, with alteration of the first sound at the impulse, and an accentuation of the aortic second sound at the base. Albuminuric retinitis with hæmorrhages was intense, and the star figure was a striking feature from the time when she was first seen in the out-patients' department three months before death, which, with a hard pulse and absence of cedema, made the diagnosis of small white kidney almost certain. A fair amount of pale alkaline urine was passed throughout; the specific gravity varied from 1005 to 1010. Albuminuria to the extent of 0.2 per cent. average was constant. A termination from uræmia was expected, but acute abdominal pain supervened suddenly, when a hard mass could be felt in the umbilical region. No blood or mucus was passed, and an enema produced a small result. Consciousness was preserved almost to the end, and no convulsions or twitches occurred, death taking place two days later. Post-mortem examination disclosed the presence of an intussusception of the ileum at a point $2\frac{1}{2}$ feet above the ileo-cæcal valve as the immediate cause of death. The right kidney weighed barely 1 oz., was pale grey in colour, with a mottled surface. The capsule was thickened and very adherent, leaving a granular surface when stripped. The cortex was much diminished and almost absent in places, otherwise very little renal tissue was left, the gland being almost entirely occupied by a uniform dilatation of the calices with thickened smooth walls, containing a turbid fluid. The pelvis was dilated and the vessels were thickened. The ureter was uniformly enlarged to the size of a pencil. The left kidney weighed 3 oz., was pale in colour, and of unusual shape, triangular in section owing to an apparent hypertrophy of the upper pole. The capsule was thickened but was adherent in a few places only, leaving a finely granular surface, with dilated venæ stellatæ over the upper end. The distinction between cortex and medulla was almost entirely lost. The arterioles were thickened. The pelvis was a little dilated, but the ureter was uniformly dilated almost to the size of the little finger. The bladder wall was hypertrophied, with prominent fasciculi over its inner surface. A mild degree of cystitis was present. The urinary passages were patent throughout. No cause was found for the condition of hydronephrosis and dilatation of the ureters. There was no abnormality of the vessels, nor of the pelvis or ureter on either side. The heart weighed 12 oz. and showed considerable hypertrophy of the left ventricle, the wall being almost one inch in thickness. The root of the aorta, also its descending portion around the orifices of the intercostal arteries, showed early degenerative changes of the intima.

Dr. H. A. HAIG detailed the histological features, and Mr. TUDOR THOMAS described the retinal condition.

Multiple Superficial Tumours (?).

MR. J. W. GEARY GRANT showed a girl, 18 years of age, with multiple swellings over the face, arms, trunk, and buttocks, fresh ones appearing during the preceding fortnight. The first was noted four years ago over the left submaxillary joint; it was now vertically oval, about 2 inches by 1 inch, protruded slightly above the adjoining skin, and felt soft and semi-fluid; the skin over it appeared to be thinned. Masses elsewhere were smaller in size, and some felt almost like lax cysts, underlying thinned-out skin. All appeared to possess a brownish tinge, as though the overlying skin was pigmented. The diagnosis lay between multiple hæmorrhagic sarcomata of the skin, endotheliomata, naevi, and an unusual form of von Recklinghausen's disease. A section through one of the swellings removed from the scapular region showed a predominating connective-tissue element, with myxomatous change and evidence of œdema. Where the œdema was present the collagen fibrils took on a modified stain. There were no nervous elements to be detected. This appearance closely resembled one of the rarer types of von Recklinghausen's disease.

Bone Formation in a Laparotomy Scar.

MR. J. BERRY HAYCRAFT showed a specimen of bone formation in a laparotomy scar. In September, 1921, a laparotomy was performed on a pensioner, aged 33. A chronic ulcer was found on the anterior wall of the stomach close to the pylorus. A posterior gastro-jejunosomy was done, and the appendix was removed. Four months later a lump was noticed in the scar; it was growing and became tender and the patient was readmitted in February, 1923. A hard lump was found in the centre of the scar, about the size of a walnut, 2 inches above and a little to the left of the umbilicus. It was not adherent to the skin, and was tender on pressure. This was explored on Feb. 17th; the tissue in the centre of the scar was found to consist of a hard mass in the rectus muscle, and deep to this was a thin plate of what appeared to be bone lying between the peritoneum and the rectus muscle. It was excised, and there was no evidence of any formation of bone in any other muscle.

Prof. E. EMRYS-ROBERTS pointed out that actively proliferating fibroblasts could, as a result of environmental stimulus, give rise not only to ordinary fibroblasts, but, under certain circumstances, to myxoblasts, chondroblasts, and osteoblasts; the variants resulting from the alterations in the types of intercellular material secreted by the cells concerned. In this case the fibroblasts had developed directly into osteoblasts, without any indication of intermediary forms, in a manner similar to the development of membranous bone.

Embolism of the Central Artery of the Retina.

MR. TUDOR THOMAS showed a young man, aged 27, who had suddenly become blind in the right eye 17 days previously. On examination two days after the onset of the blindness the right eye was found to be completely blind. The fundus showed a dark-red macula, with a large area of greyish-white retina around in which the arteries were visible only as lines. The periphery of the fundus was of a normal colour, and the arteries were of a normal size. There was not much alteration in the size of the veins. The disc was white, and near its outer border was a small hæmorrhage. Seventeen days after the onset of blindness he was able to count fingers at about a metre, but there was an absolute central scotoma. The disc was white, and the arteries around the macular area were very much contracted, and in some of the branches the blood seemed to be split up into segments of red and white. The macula was visible as a red spot, with small yellow dots radiating from it in a very small circular area. The retina around the macular area was still grey in appearance, but the colour was not so pronounced as at the first examination. Above the macula were two small hæmorrhages. The margin of the disc was blurred and indefinite. The previous history of the patient did not reveal any transient attacks of blindness, and his last illness was nine years previously, when he had swellings in the neck, which appear to

have been enlarged glands. He was a collier, and had always been able to perform hard work. He stated that he occasionally had attacks of palpitation, usually brought on by excitement. Examination of the heart did not reveal any murmurs, and it appeared to be normal. The Wassermann reaction was negative. Although the appearances in this case were those of embolism of the central retinal artery, there was no clinical evidence as to the source of the embolism; it was surmised that the condition was due to spasm of the retinal arteries, with subsequent thrombosis.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

JOINT MEETING OF THE SECTIONS OF MEDICINE AND SURGERY.

THIS joint meeting was held on March 16th, Dr. H. T. BEWLEY (in the absence through illness of the President, Dr. T. G. Moorhead) in the chair. The Secretary read a paper, written by the PRESIDENT, to initiate a discussion on the subject of

HYPERTHYROIDISM: DIAGNOSIS, VARIETIES, AND TREATMENT.

Dr. Moorhead began by reviewing existing knowledge. He referred to the frequent association of persistent thymus with enlargement of the thyroid. Mental factors, such as frights, were often associated (details of two such cases of his own were given). The possibility of gastro-intestinal infection as an ætiological factor was also mentioned. As regards diagnosis, he thought that the gastro-intestinal symptoms of hyperthyroidism were those most likely to be overlooked; in obscure cases a determination of basal metabolism would decide. Lymphocytosis occurred also in simple goitre, and was valueless as a distinguishing test. Tachycardia was, in his opinion, the most constant sign. Loss of weight was also very important. The association of Graves's disease and myxœdema in the same patient was sometimes, though rarely, found. As regards prognosis, gain of weight and diminution of tachycardia under treatment were favourable signs, but in cured cases the goitre and the exophthalmos frequently persisted. He was strongly opposed to surgical treatment of the condition, believing that proper medical treatment with X rays would cure the great majority of cases.

Sir WILLIAM WHEELER said that his interest had been stimulated by visits to Kocher at Berne, and by watching the operative work of Mayo and Crile. Recent advances had made the surgical treatment of cases of hyperthyroidism safe, and the mortality was almost negligible. There were really only three types of goitre: (1) The colloid, seen in young girls, with full symmetrical neck, associated sometimes with extreme nervousness, and difficult to distinguish from hyperthyroidism. The basal metabolic rate was the only sure method of differentiation. This was the type of goitre which responded to treatment with iodine, or its derivatives, or with thyroid extract. (2) The adenomatous goitre, in which operation might be delayed, in consideration of the importance of the thyroid gland in adult life, although adenomata frequently became toxic after a period of 15 years or so. Toxic goitre differed in many respects from Graves's disease; it was more dangerous, and gave rise more certainly to degenerative changes in the viscera. (3) The hyperthyroid cases, which were regarded in a general way as Graves's disease. Surgical treatment, he thought, was more certain than any other method. X ray treatment had the drawback that if the dose was too big myxœdema followed, and if too small the patient had a relapse. Should surgery become necessary after X ray treatment, it was complicated by the presence of fibrous tissue and adhesions. The only fatal case which he had come across was a case of adenomatous goitre, which, at the time of operation, was thought to be non-toxic, although the patient died suddenly from myocardial degeneration. Measurement of the basal metabolic

rate would have led to recognition of the nature of this case.

SIR JOHN MOORE said that as physician to a girls' school with 60 pupils not a year passed without some girls being brought to him on account of enlargement of the thyroid gland. These patients did well when treated for anaemia and given regular moderate doses of thyroid extract. In the early stages of goitre he was of opinion that if the patient was made to rise, with a fixed neck, from the recumbent position the thyroid gland would be emptied.

MR. A. A. MCCONNELL said the question to him seemed to be: was it safe to treat cases by gradual destruction of the glandular tissue by X rays, or was it better to treat them at once by operation? He believed that the mortality in these cases was as great under medical as under surgical treatment.

DR. W. C. MACFETRIDGE discussed the causation of exophthalmos, which could not, he thought, be due to excess of fat in the orbit.

DR. G. E. NESBITT said that hyperthyroidism seemed to be rather rare in Dublin at present. A question of diagnosis arose in cases without enlargement of the thyroid, when a diagnosis could only be established by the measurement of the basal metabolic rate. X ray dosage was capable of almost mathematical accuracy.

DR. BEWLEY said he had noticed the frequency of colloid goitre. He did not know what the cause of the condition was, but the water-supply in Dublin had nothing to do with it, because similar cases existed all over Ireland. He had seen only one case of acute hyperthyroidism. Regarding treatment, he thought that cases of the extreme kind should be treated at first, at any rate, by rest, sedatives, and X rays. Cases of medium severity he thought were best treated by surgery. The difficulty with regard to hospital patients was that they could not spare time to undergo prolonged rest.

SECTION OF STATE MEDICINE.

AT a meeting of this section on March 23rd, Mr. T. HENNESSY, the President, being in the chair, Dr. T. P. C. KIRKPATRICK read a paper on the

Work of a Venereal Disease Treatment Centre.

He described the procedure adopted at the centre opened at Steevens's Hospital in January, 1919, under the auspices of the Corporation of Dublin and the Local Government Board. In the four years ending Dec. 31st, 1922, 4222 patients presented themselves at the clinic, of whom 743 were women and children; of these women and children 355 were suffering from syphilis. The treatment relied on was the intravenous administration of novarsenobillon, given in weekly injections over a period of eight weeks during which time 4.05 g. of the drug were given. Subsequent treatment was guided by the condition of the patient and the blood Wassermann reaction. The results on the whole had been satisfactory, and out of the 78 patients with syphilis who presented themselves at the women's department in 1919 11 had given birth to healthy children subsequent to treatment.

There was a lively discussion, in which Sir ARTHUR BALL, MR. A. CHANCE, SIR JOHN MOORE, DR. ELLA WEBB, DR. W. A. O'KELLY, DR. W. M. CROFTON, DR. W. BOXWELL, and DR. G. E. NESBITT took part.

LIVERPOOL MEDICAL INSTITUTION.

A JOINT meeting with the Manchester Medical Society was held on March 22nd, Prof. J. HILL ABRAM, the President, being in the chair.

DR. H. T. ASHBY read a paper on

Croupous Pneumonia in Children and its Complications.

He said that croupous pneumonia is a common disease at all ages of childhood after about the ninth month, before which age it is the broncho-pneumonia which

predominates. Croupous pneumonia may be classified according to the time when the physical signs make their appearance. These latter may be present at once, they may at times be delayed for a day or two, or they may never be present at all. The diagnosis of the last type is made by the history of the sudden onset, the cough, the rapid breathing, the high temperature which keeps up, and the general look of the child. Fever of obscure origin in children often turns out to be croupous pneumonia. The delirium and convulsions during a severe attack of pneumonia, especially in highly-strung children, are sometimes so marked that the disease is pronounced as being meningitis. The progress of acute croupous pneumonia in children is good in uncomplicated cases and even in the so-called chronic pneumonia the outlook is good. Tuberculosis is a rare complication of pneumonia. There is no complication to rival empyema in frequency and in seriousness. It should be a golden rule to explore any doubtful case and if pus is present the earliest possible moment for its evacuation is essential to get the best results. Empyemata in older children do well with the ordinary operation and drainage-tube, although it is often a tedious recovery and a weak lung for the future. Empyemata in young children under two years of age do very badly, and this is where some new treatment is needed. The method of aspirating the empyema seems to give the best results, and it has the advantage that the child begins to take food again well and gain strength, even though the usual open operation has to be resorted to later. The pneumococcal empyemata do better as a rule than any other kind.

MR. GEOFFREY JEFFERSON read a short paper on

Injuries to the Cervical Spine.

He confined himself in the main to those cases where concomitant nerve and spine injury were not present. He said that during the last 40 years it had been learnt to recognise and usually accurately to diagnose vertebral fractures of the lower thoracic and lumbar vertebrae, even when the fracture involves the bodies of the vertebrae alone, and the spinal canal is in no way encroached upon. In 1891 Kuemmell had drawn attention to spinal deformity resulting from previous injury. The clinical picture resembled healed spinal caries, but the clinical histories were, of course, quite different. Not so much attention, indeed very little, had been paid to the very similar cases which were seen not uncommonly in the neck. These were again sometimes compression fractures, sometimes dislocations. Mr. Jefferson referred to the pathological anatomy of the injuries, and to the conditions found at autopsy in the fatal cases. Most careful X-ray examinations are necessary for the diagnosis, and the speaker referred to certain fallacies in the clinical examination of these subjects. As for treatment, his figures showed a greatly improved mortality-rate over that usually quoted, but this was, he said, not due to any special excellence of treatment, but rather to improvements in diagnosis which led to the recognition of the slighter cases, these reducing the percentage of deaths very considerably. The death-rate in cases with complete physiological division of the cord at a high segment will probably always be enormous. Mr. Jefferson counselled against laminectomy in cervical injuries, at all events in the early stages, and pinned his faith to reduction of the broken or dislocated bones and immobilisation.

DR. G. H. LANCASHIRE read a paper on

Urticaria.

He dealt especially with the treatment of the chronic form in adults, laying stress on the importance of an initial rest, bodily and mental, in addition to diet and drugs. The value of the skin protein-reaction appeared doubtful. Clothing was a matter of importance, and, in fact, success was only obtained by attention to detail in many directions, the cause of the trouble being often complex, including a psychic factor.

Reviews and Notices of Books.

THE STORY OF DRUGS.

A Popular Exposition of their Origin, Preparations, and Commercial Importance. By HENRY C. FULLER. London: T. Werner Laurie, Ltd. 1922. Pp. 358. 15s.

THIS volume of the Century Books of Useful Science will certainly be of interest to the layman for whom it is intended, but it is equally instructive to the physician and it will, in the few places where formulæ and scientific names are used, be more easily understood by him than by the layman. In these days of big manufacturing firms and specialised medicines the doctor often knows too little of the origin of his drugs, and the information imparted by much of this book will be valuable as well as good reading.

The work consists of 14 chapters which are really a series of pleasant essays, generally independent, but with the theme of the adventures of drugs from their origin to the time they come to the consumer. The choice of subjects is thoughtful. The first chapter treats of the homes of drug-producing plants, of attempts to introduce them to fresh countries, especially to America, and of the stimulus given by the war to these attempts. Next comes the manufacture of medicines and the history of its transference from the corner shop of the apothecary to the big factory of some well-known firm. Another chapter deals with the place of patent medicines, which the writer points out would be more appropriately designated proprietary medicines. He holds that they are necessary, and under the strict rules of the Proprietary Association of America, to which all leading firms belong, are safe and beneficial. Sections on Self Medication and the Family Medicine Chest bring out the patient's point of view on a subject which, though difficult, has to be faced; those on vaccines and serum therapy, and vitamins deal clearly with these special modes of treatment. Hay fever, "the malady of strenuous America," is the only disease which receives a chapter to itself; its relation to the presence of the common ragweed (*Ambrosia artemisiifolia*) is emphasised. The chapter on the Rôle of Alcohol brings out the large part played by this drug in the preparation of other drugs, and is especially interesting in view of prohibition. Here the difficulties which have arisen and how they have been met show how great has been the social and mercantile revolution. At first the manufacture of alcohol-containing drugs was enormously increased, but gradually this has been brought down to the point where it was before prohibition was introduced; preparations bought for the sake of their alcohol have been eliminated. While the legal side of alcohol appeals to the American more than to us, that of morphia and cocaine, which is fully dealt with in a chapter called *Dope and Not Dope*, is brought home to us by recent legislation. The essay on cosmetics called *Paint, Powder, and Rouge* makes quaint appeal to all, and is instructive to the medical man, for there are many useful hints in this borderline chapter.

The style of the book is easy; the writer knows his subject well, and he gives his own accumulated experience and not some other person's knowledge. Whether he speaks of production, manufacture, or legal restrictions, or therapeutic application, there is the same convincing informal flow, interspersed with crisp advice and picturesque similes.

THE MEASUREMENT OF EMOTION.

By S. WHATELY SMITH, M.A., Editor of *Psyche*. London: Kegan Paul. 1922. Pp. 184. 10s. 6d.

THE psycho-galvanic reflex is a change in bodily resistance to electrical conduction observed in subjects to whom stimuli are experimentally applied. Veraguth in 1907 combined the word association test with observations on the reflex, the practical uses of which Golla and Prideaux have shown in this country. Mr. Whately Smith's experiments involve thousands

of observations, and he correlates the results with purely psychological conclusions already reached by other observers; for example, he shows that to forget items of experience that one would expect easily to remember is of the nature of repression and due to the negative affective tone associated with the forgotten material. The author finds that the affective tone of a word as detected by the psychogalvanometer is exerted in opposite directions; the word may be better remembered than a less intensely toned word or may be forgotten more quickly. Hence, he deduces the presence of a negative and a positive tone, though the reflex itself gives no indication of these qualities.

In reaching this conclusion and others, he has brought methods of scientific measurement to bear upon factors otherwise capable only of subjective valuation. The title of the book, however, is questionable: the psycho-galvanic reflex measures something, but there are several bridges to be built before we can assume that this something is emotion or has a one-to-one correlation with it.

CHEMICAL PHYSIOLOGY.

Fundamentals of Biochemistry in Relation to Human Physiology. By T. R. PARSONS, B.Sc. Lond., Demonstrator in Physiology in the University of Cambridge. Cambridge: W. Heffer and Sons, Ltd. 1923. Pp. 281. 10s. 6d.

THIS bird's-eye view of theoretical chemical physiology provides interesting reading to the initiated, and there does not seem any reason why it should not prove of equal interest to the student who can be persuaded to devote time to its perusal. A certain amount of overlapping with pure chemistry and pure physiology is inevitable in the presentation of a clear picture of what the author prefers to call biochemistry, but which might correctly be called chemical physiology. Mr. Parsons has a gift of clear expression, and has succeeded in introducing a remarkable quantity of information in this elementary book; the summaries, some of them in the form of tables, should prove very useful to students. The book appears from the following extract to have been rather a long time in the press: "It might be thought that the simplest and most obvious treatment for diabetes would be to supply the missing substance formed by the islands of Langerhans, but so far no extract of pancreas has been obtained which contains the active principle in a suitable form." The rather inept quotations which head some of the chapters might well be omitted from a future edition. The short bibliography at the end of each section will enable the student to pursue the subject further if he so desires. This is a book to read, and have.

JUNIOR REGIONAL GEOGRAPHIES.

By W. H. BARKER, B.Sc., F.R.G.S., and LEONARD BROOKS, M.A., F.R.G.S. Part II.: *The British Isles*. University of London Press. 1923. Pp. 174. 2s.

THIS is the second volume of a new series of regional geographies intended for use in the upper classes of elementary schools and in the lower forms of secondary schools. The British schoolboy may regard himself as happy in having such an attractive guide to his home land. The manual is divided into 15 chapters, starting with the home as the central point of geographical interest, passing on to the consideration of islands and seas, highlands and lowlands, food and climate, then to the features of special areas, and concluding with two chapters on communications and the relations of Britain to the world outside. There are 48 illustrations and maps, the most striking being a series of typical landscapes taken from the air: an agricultural village, a highland scene, a garden suburb, the surroundings of a dockyard. The book should realise the authors' hope that it will prove useful wherever young students are making a first regional study of their own country.

LA GOUTTE.

Sur quelques points controversés ou mal connus de son histoire. By CH. FINCK. Paris: L'Expansion Scientifique Française. 1922. Pp. 80. Fr.4.50.

This little pamphlet sets out the views of one of the physicians at Vittel, on the pathology of gout and other chronic arthritic diseases. Whilst depending more on clinical than on post-mortem experience, and so lacking that exactitude which is required of data if final judgment is to be made, it will be read with interest by those who have made a special study of balneotherapy.

THE OMNIPOTENT SELF.

By PAUL BOUSFIELD, M.R.C.S. Eng., L.R.C.P. Lond., Physician to the London Neurological Clinic. Author of "The Elements of Practical Psycho-analysis." London: Kegan Paul. 1923. Pp. 171. 5s.

WRITTEN in popular style, this book gives a brief account of unconscious processes before coming to the main theme, which is that many troubles in life depend upon Narcissism or unwitting selfishness. This is to be overcome by a method of introspection—claimed to rest upon psycho-analytic principles—followed by a process of readjustment, aided by auto-suggestion along the lines made familiar by Mr. Coué. The efficacy of the method does not seem to be established, but the attempt is not likely to do harm. The fulsome recommendation on the wrapper is unsuitable in connexion with a book written for lay readers by a medical man, and doubtless the author is not responsible therefor.

JOURNALS.

IN the JOURNAL OF THE ROYAL NAVAL MEDICAL SERVICE for January Surgeon Rear-Admiral J. Shand, as a result of his long experience, tells us that in China the round worm is a powerful agent in the extension of tuberculosis, and that many other diseases which are met on that station can also be cured by the administration of *santonin* by itself. He quotes particularly cases of neuritis and asthma of two or three years' standing.—Surgeon Commander R. H. McGiffin is anxious that the treatment of syphilis shall be standardised, somewhat on the lines proposed by Surgeon Captain L. Kilroy in an earlier number (THE LANCET, Dec. 31st, 1921). In his own ship he gives to every man with a positive Wassermann reaction two sulfarsenol courses, each of eight fortnightly subcutaneous injections (0.48 g. in each of the first six, 0.6 g. in each of the two later); each course is followed by three months' rest, when a W.R. is again taken. Two consecutive negative W.R.'s must be obtained before the patient is discharged as needing no more treatment. In the 40 cases of which Commander McGiffin reports he got his negative results in all but one, and that patient left the ship too soon—in four months. Intravenous medication is recommended in hospital, but subcutaneous in ships, the method being more convenient and painless. As to intramuscular injection, "patients sooner or later refuse to have it."

BRITISH JOURNAL OF CHILDREN'S DISEASES. Vol. XX. January-March, 1923.—Dr. Leonard Findlay contributes a paper on the Treatment of Congenital Hypertrophic Pyloric Stenosis: Medicine Versus Surgery, based on observations on 62 hospital cases and 18 cases seen in private practice. His conclusions are as follows: 1. Spasm of the hypertrophied pylorus is the most important factor in causing the symptoms. 2. The results of treatment are invariably better in private than in hospital practice. 3. Medical measures give as good, if not better, results than operation. 4. Operation should probably be reserved for the youngest cases, and for those seen soon after the onset of the symptoms. 5. The great danger to

be avoided in any form of treatment is underfeeding. 6. The infant with congenital hypertrophic pyloric stenosis requires constant and individual care.—Dr. J. D. Rolleston records a case of Hereditary Tylosis, otherwise known as *keratoderma palmaris et plantaris hereditaria*, *keratoma palmare et plantare*, congenital ichthyosis, and *acrokeratoderma*, of which he remarks that though the condition is well known to dermatologists, it has received little attention in pædiatric literature. The patient, a girl aged 2 years, showed a symmetrical thickening of the epidermis of the palms and soles, the thickening ending abruptly at the border of the palmar and plantar surfaces, and separated from the normal skin by a narrow pinkish halo. The condition had been first noted a few months after birth, and had gradually become more pronounced. There were no skin lesions elsewhere. The father was similarly affected, and the child represented the fifth generation affected. Rolleston has collected eight other examples of tylosis occurring in five generations, and alludes to its endemic occurrence in the island of Meleda, off the coast of Dalmatia, when it was first mistaken for leprosy.—Dr. G. Fløystrup, of Copenhagen, reports a case of Rubella Without Rash. A boy, aged 9, after exposure to infection at school developed all the symptoms of rubella, including cervical and occipital adenitis, coryza, conjunctivitis, and slight rise of temperature, but no eruption apart from a very few pale macules on the cheeks of a few hours' duration. The diagnosis was confirmed by the patient's brother developing rubella a fortnight later.—Dr. John Thomson contributes notes of a case of Extreme Recurrent Drowsiness in a Child, apparently due to hepatic disturbance. During the first six years of life the patient had attacks of dropping off to sleep in the daytime at periods varying from three weeks to six months. During the intervals he was perfectly well and happy. On examination during an attack the only abnormal signs found were a thick brown fur on the tongue, definite increase of cardiac dullness to the right, with visible epigastric pulsation and enlargement of the liver (three fingers-breadth), which was quite soft. Under treatment with bicarbonate of soda, *nux vomica*, and infusion of gentian, alternating with small doses of *calomel*, the attacks grew less frequent and ceased altogether. At the present time the patient is a strong athletic youth of 21, with a normal heart and liver.—Dr. F. Parkes Weber records a case of Raynaud's Syndrome in a Non-Syphilitic Infant with a remarkable family history. The patient was a female infant, aged 12 months, who had been suffering from recurrent attacks of Raynaud's syndrome since the age of three months. The father suffered from recurrent attacks of headache and vomiting, one brother of the father had asthma, another brother and sister had died of diabetes mellitus, and the patient's paternal grandfather, whose case had been reported in THE LANCET,¹ had thrombo-angiitis obliterans.—Dr. G. H. Sutherland describes the autopsy on a case of Congenital Aneurysm of the Pulmonary Artery, in which the diagnosis made during life was confirmed. Other congenital defects present were a supernumerary toe, fusion of the fourth and fifth digits, and a double nail in the fifth digit.—Dr. F. J. Poynton and Mr. W. Williams report a case of Sudden Death from Blocking of the Air Passages by a Caseous Gland in a boy of 9 years.—In a paper entitled Albuminuria in a Family of Children, Dr. Hazel H. Chodak Gregory gives an account of a family of four children suffering from nephritis, two at least of whom were born with albuminuria. The urine of the father and mother was free from albumin. There was no history or other evidence of congenital syphilis in the children, and the Wassermann reaction tested in the mother and three of the children was negative.—The abstracts from current literature are devoted to genito-urinary diseases and dermatology.

THE LANCET.

LONDON: SATURDAY, APRIL 7, 1923.

INSANITY AND THE CRIMINAL LAW.

THE responsibility of insane persons guilty of offences against the criminal law has always been more or less a matter of dispute between the legal and the medical professions, and the question has now entered on a more acute phase. Some eight months ago the action of the Home Secretary in the case of RONALD TRUE, who was sentenced to death for the murder of a prostitute and was reprieved after a statutory inquiry into his mental condition, gave rise to an emotional expression in the public press, in Parliament, and even on the judicial bench. The reaction on public feeling showed a curious resemblance to the effect produced in the middle of the last century by the acquittal, on the ground of insanity, of the lunatic M'NAUGHTON, who murdered Sir ROBERT PEEL'S private secretary. Nor was this the only feature common to the two causes célèbres. In the M'Naughton case the House of Lords took the unusual course of inviting from the bench of judges a statement of the law regarding the limits and the mode of presentation of the plea of insanity in criminal cases; and the answers of the judges to the queries put to them have become historic, for they furnished the basis of the test of responsibility which is accepted as authoritative in the English courts down to the present day. In the similar circumstances consequent on the discussion of the True case, and perhaps having in mind the M'Naughton precedent, the Lord Chancellor some months ago appointed a committee of legal and administrative experts, under the chairmanship of Lord Justice ATKIN, "to consider and report upon what changes, if any, are desirable in the existing law, practice, and procedure relating to criminal trials in which the plea of insanity as a defence is raised, and whether any and, if so, what changes should be made to the existing law and practice respecting cases falling within the provisions of Section 2, Sub-section 4, of the Criminal Lunatics Act, 1884." The importance of a clear and adequate presentation of medical opinion on the matters comprised within these terms of reference was at once recognised both by the Committee and by the medical profession; and two medical organisations—the British Medical Association and the Medico-Psychological Association of Great Britain and Ireland—accordingly appointed representative subcommittees to discuss the matters at issue, and to prepare memoranda of evidence for submission to the Lord Chancellor's Committee. The text of one of these memoranda is reprinted on p. 717; the other may be read in the *British Medical Journal* of March 24th. It may, perhaps, be questioned whether on such an occasion the expression of medical opinion would not have been more effective if it had been embodied in a single document, rather than in two separate memoranda which would appear to have been prepared without joint consideration, and even to be adjusted to different points of view.

The present position regarding the criminal responsibility of insane persons is hardly of practical importance except in capital cases, for it is only in such

cases that there is a radical and irrevocable difference between the modes in which society reacts against the sane and against the insane offender; and it may be added that it is chiefly as potential homicide that the insane menace public security. This limitation was clearly in the mind of the Lord Chancellor in appointing the Atkin Committee, for the procedure under the Criminal Lunatics Act of 1884, to which attention is specially directed in the terms of reference, deals exclusively with persons under sentence of death. The memoranda take a much wider range, but it will not be necessary here to go beyond the particular problem of responsibility in cases of homicidal crime. Under the law as it exists at present, the question of the mental state of a person accused of murder may be raised on his indictment, when his fitness to plead and to understand the proceedings of the trial is decided by a jury impanelled for the purpose. Should he be found unfit to plead by reason of his condition at the time of the arraignment, he is ordered to be detained as a criminal lunatic, and no evidence is considered in proof of his guilt of the alleged act. If, on the other hand, he is found fit to plead, or if no question of his fitness is raised, the trial proceeds. If the accused now pleads guilty, he must be condemned to death, even if he be obviously insane, unless the judge—by a stretching of his authority for which there does not appear to be much legal warrant—refuses to accept the plea, and enters a plea of "Not guilty." When the plea of "Not guilty," whether entered with or without the consent of the accused, is based on a defence of insanity, it is necessary, according to the authoritative test, founded on the so-called M'Naughton Rules, to prove "that at the time of committing the act, the party accused was labouring under such a defect of reason from disease of the mind as not to know the nature and quality of the act he was doing, or, if he did know it, that he did not know he was doing what was wrong." The absurdity of this test, which makes disorder of intellect the sole criterion of insanity, has been the theme of psychiatric criticism since its formulation, and it is hardly questioned, even by jurists, that its strict application would lead to the condemnation of the majority of insane murderers. It does not have this effect, simply because most judges, when satisfied that the offender is really a lunatic, ignore or evade the test; and if, as occasionally happens, a judge fails to exercise common sense in this way, the jury will frequently reject his direction and return a verdict of "guilty but insane." In the comparatively few remaining instances, where an insane murderer has been sentenced to death, the Home Secretary has power, under the section of the Criminal Lunatics Act referred to above, to order an expert inquiry into the prisoner's mental condition, and if such inquiry shows that the convict is insane, the sentence is not carried out. In practice, therefore, there is little or no risk of a lunatic being hanged; and in fact a Committee of the Medico-Psychological Association, which considered this question exhaustively in 1896, failed to find, within the period covered by its inquiry, any instance of such a miscarriage of justice. This Committee reported that, while disapproving the existing legal test of insanity, they were unable to make any suggestions for amending the law. It is significant in connexion with the then attitude of the psychiatric experts to note that the Atkin Committee had its origin in a sense of dissatisfaction with the state of the law, not on the ground of its undue severity, but rather from a feeling that its excessive laxity threatened the public safety.

It is thus the lawyers and not the doctors who in the present instance are the primary advocates of change. This fact does not appear to have been kept adequately in view in the proposals put forward in the two medical memoranda; and it is probable that legal critics may complain that neither of these documents offers any constructive suggestions, except in regard to the mode of presenting expert evidence, which go to meet the admitted difficulty of justice in dealing with offenders on the borderline between sanity and insanity. The absence in this connexion from both memoranda of any reference to the principle of diminished responsibility, which is being adopted as a partial solution of this difficulty in other countries, weakens the statement of the medical position. On the other hand, both subcommittees have addressed themselves to the task of amending the legal test of responsibility; the memorandum of the British Medical Association proposes to add a clause recognising morbid incapacity of control as a ground of irresponsibility, and also suggests a modification of the wording of the test in regard to the power of knowing and appreciating the character of the criminal act. It is always rather risky for medical men to involve themselves in the subtleties of legal phraseology, and it is not unlikely that some member of the Lord Chancellor's Committee may be inclined to make caustic comment on the proposal that a murderer should be held irresponsible on account of mental disability, if such disability, though not interfering with his knowledge of the nature and quality of his act, prevented him from "appreciating the circumstances in which it is done"—such a circumstance, e.g., as the presence of an unobserved witness. The Medico-Psychological subcommittee seem to have been better advised in deprecating any analytical test of legal insanity, and in proposing that, instead of the M'Naughton Rules, the judge should put the issue to the jury in the form of three questions: (a) Did the prisoner commit the act alleged? (b) If he did, was he at the time insane? (c) If he was insane, has it nevertheless been proved to the satisfaction of the jury that his crime was unrelated to his mental disorder? This way of formulating the issue would allow the expert witness to give his evidence in his own language without having to obscure and distort it by translation into terms of legal technicality alien to his training and manner of thought, and it would thus make his statement of facts and conclusions far more accessible to the common sense of the jury. At the same time, without introducing any greater laxity than already exists in practice under the present system, it would remove from the English law the reproach of maintaining an obsolete, unscientific, and ineffectual formula.

A matter of equal, if not greater importance than the terms of the legal test of insanity, is the mode in which expert evidence is put before the court in cases involving this issue. On this point there is a marked divergence of opinion between the two medical subcommittees; the memorandum of the British Medical Association insists rightly and forcibly on the defects of the existing system by which expert evidence of insanity is given by ex-parte witnesses on either side, to the confusion of judge and jury, and, in the case of persons without means, possibly to the prejudice of justice; it advocates instead the provision of machinery for the independent and impartial mental examination of accused persons by a member or members of a panel of psychiatric physicians of recognised standing, whose report should be furnished to the prosecution and to the defence, and should be supported by personal evidence

in court. For some undisclosed reason the idea of impartial expert witnesses does not seem to have commended itself to the Medico-Psychological subcommittee, who devote merely a few lines to it in their memorandum, rejecting any proposal of a system of medical assessors, but admitting that "it might be possible" to appoint a panel of accredited experts, to be employed at the discretion of the court, but without interference with the existing system of ex-parte evidence. Both subcommittees are in agreement in opposing any alteration of the section of the Criminal Lunatics Act which empowers the Home Secretary to institute a statutory inquiry into the mental condition of prisoners under sentence of death. As a safeguard against possible miscarriages of justice some procedure of this sort is obviously essential, and if the enactment establishing it were repealed, popular clamour would insist on its restoration on the occurrence of the first case of doubt as to the sanity of a condemned murderer.

The memoranda also make a number of recommendations, many of them rather debatable, on matters of subsidiary importance, such as the right of appeal from the verdict of "Guilty, but insane," and the position of those unfit to plead. These memoranda represent the outcome of much painstaking labour, and they deal with questions in which the medical profession has a serious and responsible interest. On that account the conclusions will be sympathetically as well as carefully scrutinised, and any criticisms which may be passed upon them will, no doubt, be tempered by a due recognition of the extremely difficult and complex character of the questions which the subcommittees had to consider.

TUMOURS OF THE BLADDER.

URINARY disturbances of any kind, apart from what innately bad qualities they possess, bring in their trail an immense amount of physical and mental suffering. If they are irremediable, as so often happens when malignant disease has been allowed to progress too far, the plight of the victims is truly pitiable. New growths of the bladder must be included amongst the very grave urinary diseases. They possess certain characters which are seen scarcely anywhere else in the body. The papillomata, which are quite benign and local growths, show an extraordinary capacity for grafting portions of their substance on other parts of the bladder mucosa. They exhibit almost the infective characteristics of warts of the skin, in the manner in which they will give rise to satellite lesions, but, unlike the cutaneous papillomata, they unfortunately show no propensity to sudden and inexplicable disappearance. Another notable feature of bladder tumours is the fact that, to the naked eye, a malignant growth may be indistinguishable from a simple papilloma, and even under the microscope differentiation becomes possible only when the growing infiltrating margin at the base comes under view. A fortunate circumstance is that distant secondary growths occur late, or perhaps local spread gives rise to early symptoms and so calls attention to the presence of some bladder lesion. But though hæmaturia, the cardinal symptom of bladder tumours, occurs early, it is very often only an evanescent manifestation and so is apt to be disregarded.

In his lecture delivered at the Mayo Clinic, and printed in three recent issues of THE LANCET, Mr. FRANK KIDD reiterates his teaching of years, that hæmaturia necessitates cystoscopy. Even in these days the practitioner does not always follow this course, for he knows very well that many cases of

hæmaturia of renal origin, without demonstrable lesions, occur once, never to reappear. Nevertheless this is a policy dangerous to pursue, for delay may render radical treatment difficult, fraught with great risk, or altogether impossible. Mr. KIDD's views on the treatment of vesical tumours based on a personal experience of 162 cases claim great respect. Few surgeons have dealt with so many patients of whom they have accurate notes of the early and remote after-histories. That 90 per cent. of simple papillomata may be cured by Beer's fulguration method is an immense advance on the old intravesical excisions, where secondary implantation almost invariably occurred. Mr. KIDD favours the destruction of papillomata if possible at one sitting under general anaesthesia, in contrast with the multiple cauterisations which many urologists carry out. What is notable also, is the possibility of curing completely an early malignant growth by diathermy through the cystoscope. Other surgeons of less experience can corroborate this statement, although microscopic demonstration of the nature of the tumour is impossible, as it is destroyed. They would be certain to confirm the observation that some small malignant papillomata are very resistant to diathermy. The results Mr. KIDD has obtained by operative removal of malignant tumours, using a modified Squier's technique, are remarkable: 11 out of 28 patients are known to be alive and well from one to 11 years after operation. This result is not possible of achievement by the older technique of excision after cystotomy. It renders the outlook for the unfortunate sufferer from a malignant tumour of the bladder far less grave than it is commonly believed to be.

RECENT WORK ON BLOOD-SUGAR.

CARBOHYDRATES and proteins take precedence in biological chemistry over other compounds, inasmuch as they are essential to life and growth, and an additional stimulus was added to the study of carbohydrate metabolism when WILLIS showed that diabetes mellitus was associated with glycosuria. The landmarks in the growth of this knowledge are too well known to recapitulate here. Recently, however, experimental data have been published which substantially modify the existing views. First and foremost, under the inspiration of Prof. J. J. R. MACLEOD, the Toronto School have been able to produce an active pancreatic preparation, the injection of which reduces the blood-sugar and produces an intermission in the glycosuria of diabetics. Insulin is in fact the first striking success in a series of investigations, begun by MINKOWSKI when he produced diabetes by depancreatising animals, and hitherto almost fruitless. The comparative scarcity of ox pancreas has naturally led laboratory workers interested in insulin to look around for a more abundant raw material. What more natural than that they should turn to yeast, whose enzyme has been known for years to break up glucose into carbon dioxide and alcohol, a process which probably occurs also in the body. Long before the announcement of insulin physicians saw in yeast the cure of diabetes; but apart from rendering patients extremely uncomfortable with eructations, no therapeutic effect followed its administration. Early this year¹ some experimental work was published from the Biochemical Laboratory at Cambridge on solid extracts of yeast. In this Messrs. L. B. WINTER and W. SMITH put forward a new theory of the causation of

diabetes. They state that the sugar present in normal blood is an unstable form, which they call γ -glucose. In diabetic blood they find only stable forms of glucose, and from this they conclude that the pancreatic internal secretion—and probably insulin—act by converting the stable into the unstable glucose, thus rendering it suitable for metabolism. They also suggest that yeast may act in this way, for injections into rabbits lowered the blood-sugar and put rabbits into convulsions. These experiments raised the hopes of clinicians, who could see large quantities of this "yeast insulin" being available for clinical trial in the near future. The investigators themselves were guarded in their statements, and much work remains to be done before definite conclusions can be reached. Substances, such as peptone and certain proteins, all of which are contained in yeast, are known to lower the blood-sugar on injection.

With regard to the theory of stable blood-sugar in diabetes it is true that glucose, containing as it does asymmetric carbon atoms, can exist in many isomeric forms. TANRET, who discovered two distinct forms possessing different rotatory powers, showed that when α -glucose was dissolved in water, its rotatory power fell to a constant figure, and that β -glucose, when treated similarly, gave a rising rotatory power. He also found a third substance, which he called γ -glucose, of constant rotatory power. But as knowledge grew it turned out that in solution α - and β -glucose changed into each other, until a definite point of equilibrium was reached, and that γ -glucose was nothing more nor less than a mixture of these two substances in equilibrium. This fact, now admitted by TANRET himself, is difficult to reconcile with the new theory of diabetes. The constant change in solution of carbohydrates is a beautiful example of the adaptation of organic compounds to the use of the living organism. Enzymes are extraordinarily specific with regard to their action on these carbohydrate isomers. One enzyme will only act on β -glucose, and, but for this process of mutarotation, no carbohydrate metabolism would be possible. If only the α form is supplied, this goes into solution and at once dissociates into β -glucose, until a definite equilibrium point is reached between the two bodies. The enzymes then remove some of the metabolisable compound, with the result that the equilibrium is upset; more of the α form dissociates to the β compound, which in turn is removed. Thus the process goes on until all has been metabolised. No enzyme is necessary to convert α - into β -glucose, for nature has already provided a spontaneous means in this process of mutarotation. Had Prof. LOWRY, speaking at the recent Pasteur evening of the Royal Society of Medicine, overlooked this phenomenon when he condemned ALICE to a glycosuric death when she entered the realm beyond the looking-glass? For he pointed out that her enzymes being reversed could only act on *lævo*-compounds. But even if the looking-glass did not also reverse the carbohydrate molecules—and why should it not?—mutarotation must have saved ALICE from becoming diabetic.

On p. 715 of our present issue Dr. H. F. MOORE gives a useful conspectus of the views at present current as to the physiological effects which insulin has on the body. It has now been placed beyond doubt that insulin reduces the blood-sugar; unless, indeed, its administration is controlled the reduction may go so far as to endanger the well-being and even the life of the animal. In the diabetic, coincident with the reduction of the hyperglycæmia, there is a reduction of the formation of acetone and other

¹ Brit. Med. Jour., Jan. 6th, 1923.

disorderly products of metabolism. It is easy to see that in insulin the practitioner may have a powerful drug with which to control diabetes. The cost of the preparation is high, but progress is being made in perfecting the preparation, and it may confidently be stated that in the near future a supply of potent insulin will be on the market for general use. But the scientific side of the investigation should not be forgotten. We have no certain knowledge as to what happens in the body under the influence of insulin. Blood-sugar is reduced and the irregular metabolism of fat is corrected, but we do not know what becomes of the sugar. It is often stated that the sugar is oxidised, but there is no unequivocal evidence in support thereof. The statement probably originates from the belief, long current among physiologists, that diabetes is a disease in which the body is unable, more or less, to oxidise glucose, and that the degree of diabetes is proportional to this disability. This statement again is not based upon perfectly satisfactory evidence; or rather, the evidence available is susceptible of other interpretations. It is known that the liver of diabetic patients is unable to store glucose, and it is possible that the principal effect of insulin lies in its power of restoring this capacity. There is another and wider aspect of the question. Enthusiasm for a new and valuable remedy for diabetes must not lead to any slackening of the search for the causation of the disease. It is possible to produce an artificial diabetes in animals by partial or total excision of the pancreas, and definite lesions of this organ have been demonstrated in autopsies in diabetic patients. Further, the metabolism of sugar may undoubtedly be controlled by an extract of pancreas. Nevertheless, it is by no means certain that diabetes is invariably a disease of the pancreas. It must be admitted that in a large proportion of patients dying from diabetes no lesions of the islets of Langerhans can be discovered, though, taking into consideration the fact that diabetes is not an acute disease, their presence might well be expected were the pancreas the organ essentially at fault. There is a gap between the results obtained by what is crude experiment and the accumulated post-mortem observations on cases dead of the disease. The morbid processes are evidently much more subtle than is generally understood, and until the experimental results can be fitted logically into the pathological picture the essential pathology of the disease will remain a mystery.

ROYAL PORTSMOUTH HOSPITAL.—The report for 1922, presented at the annual meeting of subscribers held at the Town Hall on March 22nd, stated that as the result of the efforts of the Southsea Carnival and Mayor's Charities Committees the sum of £8000 had been raised. The ordinary income amounted to £15,982 10s. 8d. and expenditure to £20,071 13s. 2d., leaving a deficit of £4089 2s. 6d. The sum of £939 9s. was received from surplus funds of approved societies. The Voluntary Hospitals Commission granted £1965. A large proportion of the beds is devoted to surgical work; the applications for surgical treatment far outnumber those for medical relief. The work in the out-patients' department has steadily progressed. The department is increasingly used as a consultative clinic. The venereal diseases department has again to record a decreased number of new patients and decreased attendances of both male and female patients. The incidence of venereal disease in Portsmouth appears to be diminishing; for this department 3480 pathological examinations were made; for the general work of the hospital there were 1185 examinations. The average cost per bed occupied was £111 7s. 5d., and the average cost of each in-patient per week was £2 2s. 8½d. The borough treasurer, who had investigated the hospital expenditure with a view of ascertaining whether the funds were dispensed economically or extravagantly, reported that the cost compared very favourably with that at other similar hospitals, and that the developments during recent years had brought this hospital to a high standard of efficiency.

Annotations.

"Ne quid nimis."

SIR JAMES DEWAR.

BY the death of Sir James Dewar, F.R.S., Director of the Davy-Faraday Research Laboratory, at the age of 81, the world of chemistry and of physics loses one of its most ingenious experimenters. At the time of his death he was both professor of experimental philosophy at Cambridge and professor of chemistry at the Royal Institution, two posts which he had held for very nearly fifty years. It was at the latter institution that Sir James Dewar did the experimental work which was to bring him fame, and the work of a public nature in connexion with the famous lectures given there must have made him known to thousands of scientific people. The Friday evening lectures of the Royal Institution have filled a unique place among scientific activities and have been an inspiration to many, especially in their earlier years. It was due in very large measure to the care that the Director took that the lecturer's experiments should not fail, that the high standard set in these lectures was maintained for so many years. A first experience of an evening at the Royal Institution is connected in many minds with the presence of the small, alert, grey-headed figure of the Director, alert to see that all went well.

Dewar's life was practically devoted to experimental work and he tackled many problems necessitating the highest skill for their solution. He is best known for his early works on the liquefaction of the rare gases, and he was very largely responsible for the rapidity with which the list of "permanent gases" was reduced until hydrogen was the last remaining one, and this he had the satisfaction of liquefying. Shortly after this success, the gas helium was discovered and great difficulty was found in reducing it to the liquid state. It was done in the cryogenic laboratory at Leyden under Prof. Kamerlingh Onnes in 1908. The production of liquid air and other gases for commercial purposes was made possible by Dewar's invention of the vacuum vessel, which had quite a long innings in the laboratory before its adoption as a domestic article. His work on the attainment of low vacua by means of charcoal showed that his experimental genius was equally well able to deal with gas problems at either end of the scale of pressure. It is probably true to say that the problems which were solved at the height of Dewar's powers in the Davy-Faraday Laboratory of the Royal Institution, in association with the staff which he gathered about him, could have been tackled nowhere else in the country. Some of his early work had a medical aspect, for he collaborated with Prof. McKendrick on the physiological actions of light; for the rest it was one long record of scientific work of a high order, exhibiting a strong inventiveness throughout. He was the joint inventor of cordite.

He received many honours, including the Rumford, the Davy, and the Copley medals of the Royal Society, the Lavoisier prize of the French Academy, and the Hodgson medal of the Smithsonian Institution.

THE LONDON SCHOOL OF HYGIENE.

THE realisation of the London School of Hygiene comes a stage nearer with the announcement that the King and Queen are expected to lay the foundation-stone of the building some time during the month of May. It is already ten years since the institution of such a school was pressed upon the University of London by its Board of Studies of Hygiene. A recent conference between representatives of the Ministry of Health, the University of London, and the Rockefeller Foundation decided the appointment of a transitional executive committee to arrange for coördination with other interested authorities, to evolve the organisation in detail of the School, and to

develop such detailed plans that construction can be begun. The Rockefeller Foundation having undertaken to provide immediately a sum not exceeding £4000 per annum towards the salary and expenses of a director, a provisional appointment to this office will shortly be made, the occupant to act in an advisory capacity to the transitional executive committee. The official public health service in this country is satisfied of the immense value to the health of the community likely to be achieved by the establishment of a central endowed school of hygiene, which also carries in its hands the future of the London School of Tropical Medicine: for it is unthinkable that the great centre of tropical study, built up on the Mansonian tradition, will not become an integral part of the larger scheme. It has, we believe, already been accepted that the Tropical School is to retain its curriculum and policy under the guidance of its present Board of Studies and School Committee. Departmental division into pathology, helminthology, protozoology, and entomology has already produced great results, and progress has been fostered by continuous research work in the tropics and frequent expeditions. No doubt the clinical side of tropical medicine will be best served by leaving the hospital for tropical diseases where it now is, to function as a post-graduate teaching hospital. For this purpose some improvement in equipment will be necessary, so that clinical teaching may be carried out to the best advantage. The appointment of a liaison officer between the Tropical Hospital and the School of Hygiene will be desirable, until the link between the two becomes so close as to render this superfluous. We have no doubt that both as to the personnel of the Executive Committee and the personality of the temporary director, these great and not necessarily conflicting interests will be considered.

PRACTICAL POINTS IN THE ADMINISTRATION OF ANTIDIPHThERIC SERUM.

COMMENTING on the recent recommendation of the Ministry of Health that 8000 units of antitoxin should be given in every suspected case of diphtheria without waiting for the bacteriological confirmation of the diagnosis, Dr. Claude Ker, in an article which appeared in our columns last week, complains that the high mortality of diphtheria is due to a want of appreciation on the part of the general practitioner of the importance of early injection of antitoxin. This reluctance has been aggravated within the last ten years by the bugbear of anaphylaxis, the risks of which have been greatly exaggerated. Although large initial doses are necessary in severe cases, in mild and moderate attacks a very much smaller dose is required. Dr. Ker makes the valuable suggestion that 2000 or 3000 units should be injected as a routine practice by the practitioner whenever he thinks it necessary to take a swab, and is convinced that such a practice would be followed by a considerable fall in the case-mortality of diphtheria. The intravenous injection of diphtheria antitoxin, on which we publish a note in this issue by Dr. Poul Iversen, of the Blegdams Hospital, Copenhagen, has been practised for many years on the Continent and in the United States, but has never been very popular in this country, although it was recommended more than 20 years ago in THE LANCET by Dr. D. L. Cairns,¹ and two years later by Dr. J. Biernacki and Dr. J. C. Muir.² The reluctance to employ what is theoretically the best method, inasmuch as it enables the antitoxin to be introduced directly into the circulation, is due to a number of causes. In the first place, intravenous injection in small children, who constitute the majority of the severe cases in which this method is specially indicated, is often fraught with considerable difficulty and may require dissection under an anæsthetic, as was done by Biernacki and Muir. It is for this reason that Dr. Ker reserves intravenous therapy in diphtheria for adults and older children, whose veins allow the easy introduction of a needle. Dr. Iversen does not give any

details as to the ages of his patients, but implies that the technique does not present any difficulties. Secondly, a special preparation of antitoxin is required, containing a lower percentage of antiseptic than is usually employed. In the present series 1 per cent. chinolol was used in place of phenol. Thirdly, the possibility of a severe reaction, which occurred in 27 patients, or 7 per cent. of Dr. Iversen's cases, acts as a deterrent. In most of the cases in the present series the symptoms took the form of a rigor lasting from 10 to 30 minutes, during which the pulse was small and the patient blanched. More rarely the rigor was absent and the condition resembled a mild collapse. The symptoms, however, were only transient, and were relieved by the injection of camphor. Anaphylactic symptoms, consisting in a rigor or collapse, profuse urticaria, œdema of the face, and pain in the joints, are especially likely to occur after intravenous injection in cases which have received serum some time before, nor are the symptoms always prevented by a desensitising dose. In view of all these drawbacks it is not surprising that intravenous therapy in diphtheria has not found more supporters. Dr. Iversen, however, writes with such conviction of the superiority of intravenous injection, that we should welcome a record of the experience of those of our readers who have had an opportunity of making similar observations.

THE DICKINSON SCHOLARSHIPS.

A LARGE capital sum, conveyed to trustees under the will of the late Mrs. Conradine Sophia Dickinson, of Bournemouth, has enabled them to institute a number of scholarships in the Manchester Medical School, which are shortly to be awarded for the first time. The Anatomy Scholarship is of the annual value of £25 awarded for one year to the student who distinguishes himself most in the first-year course in anatomy at Manchester University. The Surgery Scholarship of £75 is offered in alternate years to graduates in medicine and surgery of Manchester University, the successful candidate undertaking to carry out some piece of special research approved by the medical board of the infirmary. The Pathology Scholarship of £75 is similarly open to graduates who undertake to work for one year in the pathological laboratory of the University under the direction of the professor of pathology. In addition to these a Research Travelling Scholarship in Medicine, of the value of £300 tenable for one year, is available annually for a distinguished graduate of not more than three years' standing. Candidates are required to submit to the trustees evidence of ability and special knowledge, and may have to undergo a special examination. The Travelling Scholar is required to undertake further study in original work at Paris or another medical school outside the United Kingdom. Applications for any of these scholarships should be made to Mr. F. G. Hazell, Secretary to the Trustees at the Royal Infirmary, Manchester, from whom a copy of the regulations can be obtained.

HOSPITAL ALMONERS.

THE Institute of Hospital Almoners in its annual report just issued pays tribute to the pioneer work of the late Sir Charles Stewart Loch, Tooke Professor of Economic Science and Statistics in King's College, London. It was Loch's intimate study of the working of the out-patient departments of London hospitals which led to the movement for social service in connexion with hospitals and resulted in the first appointment of almoners. The report raises the question whether, at a time when hospital finance is so difficult, it is justifiable to spend money on an almoner's department, and it answers the question by demonstrating how the employment of experienced people will readily recoup a hospital for the additional outlay. The Institute itself sets a high standard in regard to training, and only ten certificates were issued during the year 1922, although now, as always, the demand for trained almoners exceeds the supply.

¹ THE LANCET, Dec. 20th, 1902, p. 1685.

² Ibid., Dec. 24th, 1904, p. 1774.

The Council of the Institute is confident that not enough women are entering upon this work to fill the vacancies that are likely to arise. The course of training begins in the spring of each year, extends over a minimum of two years, and involves an inclusive fee of 40 guineas. The first four months are spent in an office of the Charity Organisation Society in London; the next nine months under the direction of the Ratan Tata Foundation in acquiring a sound basis of theoretical knowledge; a practical year follows under the direction of an almoner at a hospital training centre, two months of which must be spent in visiting other hospitals, and one month in practical work outside the hospital, such as health-visiting or attendance at an infant welfare centre. At the end of this time the almoner should be in a position to form the desired link between the hospital and the home, and to lend such co-operation as may get to the root of the difficulty which has been the cause of the illness or hinders return to health. The difficulty may be economic or temperamental; it may require assistance for the family through a local relief agency, or be only a matter of adjustment after judicious inquiry. The work is strenuous and, as the report suggests, is never likely to be highly paid: but several things point to the fact that such work is appreciated by those in a position to assess it. At the recent session of the Royal Academy of Medicine in Ireland Dr. Ella Webb drew attention to the indispensable character of the almoner's work at a venereal disease clinic. During the past year an almoner has been engaged by the Medical Research Council for special investigation into the records of social work done during the past seven years at St. Thomas's and York Road Lying-in Hospitals; and the Universities of Birmingham, Bristol, Glasgow, Leeds, and Liverpool have undertaken to take a part in the training of almoners for their own areas. It is significant that Sir Napier Burnett has accepted the presidency of the Institute.

LEAD POISONING IN INFANCY.

Dr. L. Emmett Holt, jun., of Baltimore,¹ who records an illustrative case which he observed in the Babies' Hospital, New York, remarks that, though much has been written on lead poisoning in older children, especially in Australia, the condition is very rare in infants. Arlidge in England and Constantin Paul in France, who made extensive studies of the families of workers in lead, found a very high percentage of stillbirths and a very high mortality from convulsions in the first three years of life. The number of mental defectives among the older children was also very large. Only a few undoubted instances of placental transmission of lead have been recorded. Paul admits that in many cases which he classified as congenital the poisoning may have continued after birth, through the mother's milk. Considerable quantities of lead were obtained by Ballard from the milk of a mother suffering from plumbism. A somewhat larger number of reliable reports of acquired lead poisoning in infants have been published. The sources of the lead varied considerably in different cases and consisted of toys, buns, sweets, paint on the mother's face, or ointment on the mother's breast. The prognosis in these cases largely depends upon the success with which the lead can be eliminated from the system. Dr. Holt's case was a female infant, aged 8 months, admitted to hospital for convulsions which had started on the previous day. Examination of the blood showed a moderate anaemia: red cells, 3,800,000; hæmoglobin 67 per cent. As the convulsions did not recur within the next 24 hours the mother was allowed to take the child home. Two days later repeated attacks of convulsions developed and the child was readmitted. Cutaneous tuberculin tests and the Wassermann reaction in the blood were negative. In addition to a moderate degree of anisocytosis and poikilocytosis and many nucleated

red cells, a blood smear showed a remarkably large number of red cells with basophil stippling. This finding suggested the possibility of lead poisoning, and after prolonged search it was found that the mother who was suckling the infant had been applying an ointment, the chief constituent of which was lead acetate, to her breasts for eczema. The child's convalescence was slow, being complicated successively by otitis media, prolonged diarrhoea, and pyelitis, but gradual improvement took place. No means were taken to eliminate the lead from the system, the only treatment being administration of calcium bromide to control the convulsions, which continued at intervals for about a week.

THE ANNUAL MEETING OF THE B.M.A.

ARRANGEMENTS have been completed for the holding of the ninety-first annual meeting of the British Medical Association at Portsmouth from Tuesday, July 24th, to Friday, July 27th, under the presidency of Mr. Charles Plumley Childe, F.R.C.S., senior surgeon to the Royal Portsmouth Hospital. The Presidential Address will be given on Tuesday evening and the annual exhibition of surgical appliances, foods, drugs, and books will be officially opened on the same day. The meetings of the scientific sections will be held on the next three following days. The Sections of Medicine, Surgery, Obstetrics, Pathology, and Neurology are each allotted three days; those of Ophthalmology, Public Health, Children, Laryngology, Radiology, Military Hygiene, and Tuberculosis each meet on two days, while Medical Sociology, Orthopaedics, Venereal Diseases, and Anaesthetics occupy each a single session. The Section of Medicine has chosen for discussion on successive days (1) diabetes; (2) aetiology and treatment of heart disease in early life; (3) chronic bronchitis. Subjects for the other scientific sections have yet to be announced. The annual dinner of the Association will take place in the Town Hall on Thursday at 7.30 p.m. The honorary local general secretary of the gathering is Mr. C. A. Scott Ridout, M.S., "St. Elmo," Clarendon-road, Southsea. The annual representative meeting will, as usual, precede the annual meeting on Friday, July 20th, to commence at 10 a.m., Dr. R. Wallace Henry presiding, and continue on the three following week-days. Saturday, July 28th, will be set apart for excursions to places of interest in the neighbourhood.

DISTINGUISHED ABERDONIANS.

ALTHOUGH one need not take too seriously the ancient saying attributed to an Aberdonian: "Tak awa Aberdeen and sax mile roun and whar would you be"? yet he who has read Mr. McCulloch's list¹ of celebrated graduates of Aberdeen University will acknowledge in all sober truth that in the production of sons of light and learning the northern city has done her full share. In Mr. McCulloch's list we find the following names: Francis Adams, the translator of Hippocrates and at the same time a humble practitioner of medicine in a Deeside village; John Arbuthnot, wit and physician; Alexander Bain, philosopher; James Beattie, poet; John Stuart Blackie; Hector Boece (Boyce or Boethius), the historian; Robert Brown—that prince and pioneer of botanists; James Burnett (Lord Monboddo—evolutionist), John Burton Hill, historian; Sir Andrew Clark; Sir James McKenzie Davidson; Sir Patrick Dun, the Dublin physician; James Matthews Duncan; Hugh Falconer, a great palaeontologist; Archibald Forbes; Sir William Fordyce (John Hunter's contemporary); Simon Fraser (Lord Lovat); Sir David Gill, astronomer; the gifted family of Gregorys; George Skene Keith; William MacGillivray, naturalist; Sir William MacGregor, physician

¹ American Journal of Diseases of Children, March, 1923.

¹ Viri Illustres Universitatum Aberdonensium. Compiled by W. E. McCulloch. Aberdeen: W. and W. Lindsay. 1923. Pp. 176. 3s. 6d.

and colonial administrator: Sir Patrick Manson; David Masson; James Clerk Maxwell (who, however, was merely a professorial bird of passage as far as Aberdeen was concerned); Peter Redfern; Alexander Reid, "the first lecturer on surgery in London"; Sir James Stirling; Augustus Désiré Waller. This is a list of which any university may be proud. We sincerely hope that young graduates of other universities will do as Mr. McCulloch has done, for we count it a sign of health when students of a university nurse the memory of distinguished graduates. We give the author full credit for being moved to compile this list as a labour of love. And yet, a remark he lets drop in his preface leaves us a little uncertain as to whether or not his motives may not have been a little mixed. We rather suspect he means "to down the southron," for it appears that a Cambridge undergraduate had cast aspersions on the ancient university of the north; the list is intended for the education of that undergraduate. But was the Cambridge undergraduate not merely in a playful mood when he challenged Mr. McCulloch?

THE MUSCULARIS MUCOSÆ.

THOSE medical historians who have had the advantage of living after the time of Harvey have frequently expressed astonishment that the complete circulation had remained undiscovered throughout so long a period. From Erasistratus to Fabricius all practical anatomists had been acquainted with the cardiac valvular arrangements and with the directions towards which the separate valves opened; yet the vision was kept from their eyes by virtue of that human truth, that we see as a rule only that for which we are looking, and they spent their energies in the effort to fit the facts to the theories, rather than in altering their ideas in conformity with the facts which they observed. This curious weakness of the human understanding applies to small matters as well as to large, to the microscopic as to the macroscopic. The presence of a certain special tissue with a definite function, such as muscle cells with their contractile powers, should imply of necessity that the tissue is there to exercise its function, and that the organ which contains it is so far contractile. The existence of muscle, for example, in the cerebral arteries ought to have been enough in itself to show that these vessels had vaso-motor properties, as arteries elsewhere, yet this was strenuously denied on purely negative grounds, though voices called in the wilderness never so loudly. Similar things might be said about the vessels of the lung.

There is another situation in which muscle has been known for many years, but no definite function has been assigned to it, nor reasonable explanation given of its presence. We refer to the submucous musculature, the *muscularis mucosæ*, such as is found in the stomach and intestines, and about which Prof. Gösta Forssell, of Stockholm, recently read a very interesting and important paper in the Section of Electro-Therapeutics of the Royal Society of Medicine, which was reported and illustrated in THE LANCET for March 31st. Anatomically, the *muscularis mucosæ* is a well-developed and continuous layer. In the stomach it even shows here and there a tendency to form outer and inner strata running in cross directions. It has a definite and full nerve-supply from the submucous plexus, which is itself a distinct and separate derivative of the myenteric plexus. These facts alone may be said to point strongly to some definite and important rôle which, up to the present, has not been demonstrated. The general idea of medical men concerning the matter is probably what Sir Humphry Rolleston happily expressed when he said, in the discussion, that he had previously regarded the gastro-intestinal mucosa as capable of about the same range of movement as the skin possesses in the act of "gooseflesh." Prof. Forssell has much wider conceptions than this, views of definite action and function that will, without doubt, lead to consider-

able physiological criticism. He holds that the mucous membrane is not mechanically passive, but its folds represent phases of active movement, and it is actively concerned in controlling the rate of flow along the alimentary canal and in the formation of "digestive chambers" of varying form and size, in which the material can be more intimately surrounded by the membrane. This throws on the mucous membrane a much greater responsibility for the success of the digestive processes than has been accorded to it hitherto, and is a view that calls for serious investigation and consideration. The ultimate proof must rest on experiment and direct observation; anatomical preparations are in this respect of little value, but the deductions from experiment and observation must be in accordance with anatomical fact if they are to stand. The relation of muscle cells to the central lacteal of a villus is quite in keeping with an assumed action on this channel, and there seems to be no reason why the whole strand might not also alter the shape and length of the projection; but it might be objected, for instance, if one were considering the valvulæ conniventes or folds of Kerekring, that the method of continuity of their muscular layers with the general basal stratum could only allow of a limited amount of alteration in position. However this may be, the skiagrams shown by Prof. Forssell, especially those of the jejunal loop, are very suggestive arguments for the views he adopts, and it seems to us that he has opened a new phase in the physiological study of all the factors which combine to constitute the processes of digestion.

RECENT WORK ON THE SCHICK TEST.

OBSERVERS on both sides of the Atlantic continue to make fruitful studies of diphtheria in the new light thrown by the Schick test for immunity and the method of producing immunity by toxin-antitoxin mixtures. In a recent report¹ by Surgeon-Commander Sheldon F. Dudley, R.N., he records observations on the distribution of immunity in a school of over 1000 boys and on the changes from susceptibility to immunity which occurred during outbreaks of diphtheria. He also correlates the results of the test with the incidence of cases of diphtheria and of carriers. An epidemic of scarlet fever was in progress at the same time, and he draws some conclusions as to the mode of spread applicable to both diseases. The report indicates the way in which at the present time new light is falling on the more obscure problems in the epidemiology of diphtheria. During the epidemic the finds of "morphological diphtheria bacilli" were divided among 63 cases of membranous diphtheria, 14 of non-membranous sore-throat, and 28 carriers. The Schick test carried out four months after the beginning of the epidemic revealed the fact that among the new boys entering the school at 11 to 13 years of age immunity was present in 55 per cent., and that of 764 boys, who had been at least one term in the school and been exposed to the chances of infection during the height of the epidemic, 86 per cent. gave a negative result to the test—i.e., were immune. Those boys who had been two and a half to four and a half years in the school were immune to the extent of 95 per cent. The observations made confirm the statements of other workers in finding that the Schick test is invariably positive in actual cases of diphtheria, but that in carriers the results are negative. In fact, carriers are generally considered to owe their escape from active disease to this immunity. The production of active immunity to diphtheria is a slow process. Immunising doses of toxin-antitoxin mixtures in a large percentage of those inoculated did not produce immunity (Schick-negative reaction) for eight weeks to three months. In the present series of cases of clinical diphtheria it was shown that the Schick-positive reaction during the attack had been converted into a Schick-negative in

¹ The Schick Test. Diphtheria and Scarlet Fever: A Study in Epidemiology. Medical Research Council, Special Report Series, No. 75.

only 84 per cent. four months after the attack, though later this was found to have risen to 92 per cent.

The interesting question arises, by what exact means a susceptible new boy becomes immunised. At first sight it would seem probable that this change was effected by the boy receiving a slight superficial infection and becoming a temporary carrier, since it is known that many such carriers are often present in epidemics. The difficulty lies in the fact that Schick-positive carriers of virulent bacilli are unknown. Commander Dudley thinks that immunity is developed as the result of the frequent reception and rapid destruction of diphtheria bacilli in numbers insufficient to cause actual clinical disease or to be detected bacteriologically, as in the case of a carrier. He believes that in fact during an outbreak three "epidemics" are in progress simultaneously: (1) of clinical diphtheria, (2) of bacteriological carriers, and (3) an immunising epidemic of subpathogenic natural "inoculations" which are only recognisable by their results. This hypothetical immunising process he expands as a theory of the spread of infection in other diseases also—e.g., scarlet fever. He considers the relation of the reception of the pathogenic agent to that of its destruction is the determining factor in infection. If the reception goes on faster than the destruction, the virus accumulates till present in a sufficient dose to infect. This hypothesis agrees with the much greater danger of infection from proximity of susceptible individuals to the infective cases or the carriers during the night, since the eight or more hours of exposure allow a considerable accumulation of infective material, if the virus received is being destroyed at a relatively low rate. In this connexion the "spacing out" of beds, so successfully practised by J. A. Glover in the case of meningococcus carriers during the war, is dwelt on in some detail as applied to diphtheria, scarlet fever, &c. In the school concerned the distance between the beds was only 1 ft. 9 in., and it is claimed that certain non-pathogenic bacteria—e.g., Hoffmann's bacillus as well as the scarlet fever virus—were spread mainly during the night. This thesis is supported by reference to plans of the bedrooms. A plan showing the distribution of the beds in which cases of diphtheria occurred affords no evidence of spread in the dormitory, but other considerations and the probability of intermediate carriers lead the author to look upon the bedroom as the place where transmission usually occurred. On the other hand, strong evidence is brought forward that the first cases actually contracted their infection in the class-rooms by means of penholders sucked by dangerous carriers and then, during the next lessons, used by the members of another class in the same room. Virulent *B. diphtheriae* were experimentally deposited on a penholder in this way and later, after lying for a fortnight in a cupboard, were cultured and shown to be both viable and virulent. Complete records of epidemics in which carriers are systematically sought for and the Schick test is made and repeated later, together with other epidemiological factors, will no doubt serve to clear up the points which are still at issue. Commander Dudley's report concludes with valuable observations and conclusions on the nature of the Schick "pseudo-reaction."

Characteristic energy has been shown by some public health departments in America and large numbers of children have been tested and the Schick-positive (susceptible) immunised with toxin-antitoxin mixtures (T.A.T.). Moreover, the subsequent histories of the children have been followed up as regards immunity and attacks of diphtheria. In March, 1922, Park reported that among 90,000 children in New York who were known to be Schick-negative (immune), either naturally (57,000) or as the result of immunisation (33,000), 18 cases of diphtheria had occurred, as against 56 cases among 90,000 untreated control children; a rate of morbidity reduced to one-quarter. Dr. John Ceconi now records² the results of about

26,000 Schick tests made in Boston during six months in 1922. Of a series of 20,713 children tested 19,148 came up for examination and the results were "read"; 9983 were found to be Schick-positive (susceptible), and of these 7013 (70 per cent.) received three T.A.T. doses. The results of applying the test again ("re-Schicking") six months later were known in the case of 300 at the date of publication and showed a change from positive to negative in over 95 per cent. What change in immunity would have occurred naturally without inoculation can only be inferred from the general results of the Schick test, but there is no reason to suppose that it would have been considerable. The prevalence of diphtheria bacilli at the period covered appears to have been very low. Examination of swabs from 1663 Schick-positive children yielded 6.2 per cent. of cultures of *B. diphtheriae*, all of which were non-virulent, and 1000 Schick-negative children yielded 5.7 per cent., also all non-virulent. The stimulus to the production of natural immunity by contact does not therefore seem to have been present to any great extent. It is pointed out that the effect of immunisation is not an increase in the number of carriers as some have feared would be the case. In a statistical report on the same date by Dr. Paul Eaton it is stated that the percentage of susceptibles may vary from 15.2 to 72 per cent. in crowded and thinly populated districts respectively. The cause of "pseudo" or "protein" reactions following the Schick test inoculation is not attributed mainly to a sensitiveness to the protein of the bacillus itself, but experiments on this point are stated to be in progress. The work in Boston is being carried out with a staff of eight physicians and seven nurses, and is presumably being continued with equal vigour. The effect of these attempts to prevent diphtheria by immunising the susceptible should be still more apparent in a few years.

THE ACTION OF QUINIDINE ON ACUTE GOITRE.

QUINIDINE, which has recently sprung into prominence on account of its dramatic effects in certain forms of heart disease, seems to have other spheres of usefulness, as a recent paper by Dr. E. Benhamou¹ shows. The case he records is certainly striking. A woman, aged 45, whose mother was rheumatic and father tuberculous, had suffered at the age of 17 from rheumatism of the left knee, lasting for six months. Off and on she had suffered from rheumatic pains, and she had been a little short of breath, although there were no auscultatory signs of disease. The sudden onset of the menopause, a few months before she came under treatment with quinidine, was promptly followed by her first attack of essential, paroxysmal tachycardia, which lasted half an hour. The second attack, which occurred a month later, was a little longer and more distressing. Gradually the intervals between each attack became shorter until they were continuous, and the dyspnoea and cardiac distress were such that she was completely invalided. A goitre, which had lasted for some time, but which had hitherto been small, now began to grow rapidly, pulsating and threatening to suffocate her. On examination she was found to be suffering from severe incessant tachyarrhythmia with asystole; the pulse was very rapid and irregular, the cardiac and liver dullness was increased, the bases of both lungs were congested, the lower limbs were swollen, and there was oliguria with paroxysmal dyspnoea. The pulsation of both goitre and heart was most embarrassing, and the general condition was alarming. The exhibition of digitalis had a beneficial effect on the asystole, diuresis, and respiration, but the tachyarrhythmia with its concomitant discomfort persisted unmodified even after digitalis had been given for eight days. Quinidine sulphate was now given, the total quantity on the first day being 0.6 g. Improvement instantly followed, and by the second day the pulse had fallen to 80 and was more regular. The same dosage was continued, and when it was reduced

² Report of Progress on the Schick Toxin-antitoxin Activities of Boston Health Dept. By John A. Ceconi, M.D. And a Statistical Report on the same by Paul Eaton, M.D. Boston Med. and Surg. Jour., clxxxviii., No. 4, pp. 94-99, Jan. 25th, 1923.

¹ Paris Médical, March 10th, 1923.

to 0.4 g., the pulse-rate began again to rise. After eight days the supply of quinidine ran out, and for the next three days, during which no quinidine was given, there were two attacks of tachycardia. The resumption of the quinidine medication promptly restored the former rhythm. After 25 days it was necessary to give quinidine only every second or third day. The patient was able to return to her usual occupations, and what was still more remarkable than her cardiovascular recovery was the almost complete disappearance of the goitre; it was even smaller than it had been before the menopause. This case is also instructive as showing the differences in the spheres of usefulness of digitalis and quinidine respectively.

PRIMARY CANCER OF THE PLEURA IN HUSBAND AND WIFE.

SYNCHRONOUSLY with the publication of *Acta Medica Scandinavica* for Feb. 22nd, 1923, there has been issued a supplement containing the transactions of the Tenth Northern Congress for Internal Medicine, held in Helsingfors in the summer of 1921. Among the interesting papers in this bulky supplement, there is one by Dr. Arnold Josefson with the above heading. In March, 1911, he was consulted by a man, aged 55, of German extraction, who had suffered for some weeks from dyspnoea. There was a history of gout, but not of syphilis. A pleural effusion on the right side was aspirated thrice in 1911, the fluid being blood-stained. The X rays showed a dense shadow over the lower two-thirds of the right lung. There was no history of cancer in the family. In March, 1912, metastatic tumours were found in the right twelfth rib and in the neighbourhood of the gall-bladder. Some time afterwards metastases were also found in two other ribs, one on the right side and one on the left. Herpes zoster developed on the right side of the chest in May, and death occurred in July, 1912, after an illness of 16 months. In March, 1921, his wife, a Swede, aged 62, complained of shortness of breath. A pleural effusion on the right side was found, and almost two litres of blood-stained fluid were aspirated. Within two months she was dead. The necropsy showed primary cancer of the right pleura with metastases in the great omentum, the peritoneum, and the retroperitoneal lymphatic glands. Dr. Josefson raises the following questions: Did one patient infect the other? Was the cancer caused by one and the same virus? Was the matter merely a coincidence? Could the wife have harboured the virus all these years without being aware of it? Whatever the answers may be, such a case of cancer *à deux* is very remarkable. Whether it is unique, as Dr. Josefson claims, is doubtful, but at any rate the coincidence is sufficiently rare to justify the suspicion that it was purely accidental. Had these cases been an example of contagion, one would have expected the skin rather than the pleura to have been the seat of the primary disease. Dr. Josefson finds it impossible to dismiss the view that there may have been a common, external cause, and he concludes: "Granted that we are going in the wrong direction, would it not be advisable, with the knowledge which I have here emphasised, to proceed on the same radical lines with regard to cancer as to tuberculosis?" Though he knows of no case of the attendants of a patient becoming infected by the latter's cancer, he holds that patients suffering from cancer should be isolated, and that the bedding and dwellings of patients suffering from cancer should be disinfected when they are no longer used by the patient. With regard to his advocacy of isolation, he will assuredly find many dissentients in the foremost ranks of the medical profession.

THE Sixth Silvanus Thompson Memorial Lecture will be delivered by Dr. C. Thurstan Holland at a general meeting of the Röntgen Society to be held on Tuesday, May 1st.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

XIV.

THE TREATMENT OF CLUB-FOOT IN THE NEWLY BORN.

THE only type of club-foot which is likely to offer difficulties to the practitioner is talipes equino-varus. The other congenital varieties are easily dealt with. Congenital calcaneus is not accompanied at first with any appreciable weakness of the calf muscles, and its treatment necessitates mere fixation of the foot in the position of equino-varus for about six weeks. If the deformity is not easily overcome by immediate manipulation it can be effected in two or three stages and the recovery is assured as soon as the child can voluntarily plantar flex the ankle. A pure talipes varus is rare and is slightly more obstinate, but the treatment consists in fixing the ankle in eversion. Here again recovery is complete only when the peronei act voluntarily.

Talipes Equino-varus.

Our problem is in connexion with talipes equino-varus, and our difficulties are mainly influenced by its duration and severity, or both. The primary distortion of equino-varus is a dislocation inwards of the anterior part of the foot at the medio-tarsal joint and an inward deviation of the os calcis, with shortening of the calf muscles. The deformity increases from week to week in the untreated case. The scaphoid articulates with the side of the head of the astragalus instead of with its anterior surface; it also lies more towards the under side of the astragalus and thus leaves the head of the astragalus more or less uncovered. The cuneiforms and metatarsals follow the direction of the scaphoid. The cuboid lies somewhat to the inner side of the anterior part of the os calcis. In a certain proportion of cases there is an internal rotation of the tibia and fibula. In the early cases the main obstructions to the reduction of deformity are the plantar fascia and the structures which bind together the os calcis, astragalus, and internal malleolus.

The question is often asked, "When should treatment be commenced?" and the answer varies from "Immediately" to "When the child commences to walk." On this point I desire to be very definite. In my opinion *treatment should commence at once*. Delay adds enormously to our difficulties. When we remember that at the very earliest appearance of the baby a certain displacement of the bones exists, we can understand that every week of growth fixes and increases these bony changes. A great responsibility attaches to the medical man who counsels delay. The blame cannot be thrown upon the midwife, for she invariably calls attention to the defect. To any surgeon of practical experience it is hardly necessary to state that a baby of one day old is an infinitely easier problem than that of a month old, and that after a few months the deformity may require very skilled and somewhat forcible effort. I have never met with a case where treatment has been started in the first week where the deformity could not be completely rectified by manipulation and retention in two months. This, of course, does not mean that the child is cured, for reasons which I will mention later, but the foot in this short space of time can be made mobile so that it can, without effort, be placed in a position of calcaneo-valgus.

Are we able, when we see the case early, to form a reliable opinion as to whether treatment is likely to be easy or difficult? I think we are. Cases which present a heel which is short and inverted and which in addition are accompanied by marked adduction at the mid-tarsal joint are more difficult than those with

a comparatively straight inner border of the foot and a heel less deflected.

Manipulation.

The most appropriate treatment for a very early case of club-foot is that of manipulation and fixation. Division of the tendo Achillis can be avoided. The foot should be manipulated with the primary object of straightening its inner border; in other words, the anterior part of the foot should be abducted at the mid-tarsal joint. This can usually be effected in a few minutes. If it is the left foot the heel and the epiphyses at the ankle-joint should be grasped by the left hand, while manipulation is carried on by the right. When the adduction is overcome the varus deformity should be slowly rectified. This should be done as completely as possible, even to the point of over-correction. When the surgeon is satisfied that there is no resistance to outward displacement he can proceed to overcome the equinus. This he does by gripping the right ankle in the palm of his left hand, which should contain the back of the heel and the lower epiphyses of the tibia and fibula. With the foot in the valgoid position the tendo Achillis is stretched, with the right hand grasping the foot and pushing it upwards. During all these manipulations the endeavour should be to guard the epiphyses, which are easily injured in a baby, but which can always be safely protected. In cases where, in addition to equino-varus, there is a rotation of the tibia and fibula, there should be manipulation of these bones by a method which can best be described as similar to that employed in wringing a cloth—i.e., the left hand grasps the upper half of the leg, twisting it inwards, and the right hand the lower, twisting it outwards. If the tendo Achillis is very tight and the surgeon fears an injury to the epiphyses it may be divided, but in the case of a baby this is rarely required.

Division of the Tendo Achillis.

The division of the tendon is often done in very bungling fashion. The dangerous long tenotomes should be discarded for short ones, which I have often illustrated. The child should be made to lie on his face while the nurse flexes the sound limb out of the way. The position of the tendon can be felt with the handle of the knife and an indentation made with it to its side to denote its position. This is especially helpful in the case of a fat baby. The surgeon holds the foot with the left hand in a dorsiflexed position and enters the knife to the inner side of the tendon at the indentation mark made in the skin. The foot is then slackened while the blade is turned beneath the tendon, then tightened, so that by a short sawing movement the tendon is divided from before backwards. When the tendon has been divided the equinus should be at once corrected. There is no object to be gained by the gradual separation of the divided ends. The fear of non-union is practically groundless. It has only happened to me once.

Fixation.

When the foot is restored to its normal position it can be retained by bandage, adhesive strap, plaster, or appliance. In the case of a baby I prefer adhesive plaster, which is so applied as to keep the foot everted and dorsiflexed. In older children other methods are used. In using adhesive plaster care must be taken not to constrict the muscles.

The adhesive plaster should be used as follows. Apply a long strip of $\frac{1}{2}$ -inch adhesive strapping round the tread of the foot from the outer border over the dorsum and across the sole. The foot is then everted, flexed above right angles, and retained in this position by continuing the plaster to a point above the calf muscles, where it is then taken round the back of the limb just below the knee. If further eversion is required an additional short length of strapping may be applied round the ankle and including the everting piece already in situ. The strapping must be renewed as frequently as it becomes ineffective.

Surgeons will have noted that after successive manipulations knock-knee often occurs as a complication. This is due to the surgeon, who has allowed the internal lateral ligament of the knee to be stretched. To prevent this the knee-joint should be protected by an assistant while the feet are stretched.

We have seen that treatment should be started at once and should be continued until the patient can voluntarily place his foot into eversion and dorsiflexion. The cure is only finally completed when the patient can walk.

The Avoidance of So-called Relapses.

There are three causes of so-called "relapse" in club-foot: (1) Insufficient correction of deformity; (2) erroneous deflection of body-weight on the foot in walking; (3) a slack and lengthened condition of the dorsiflexors and evertors of the foot due to their overstretched and semi-paralysed condition. If the deformity be not sufficiently corrected in the first instance the old condition of things is sure to return, because of the altered shape of bones and other structures, more especially the ligaments. Roughly speaking, the change in bones and ligaments on the convex aspect of the talipes has resulted in an increased surface measurement. Unless this is quite obliterated by treatment the unequal growth goes on until the so-called "recurrence" again taxes our resources.

When the time for walking comes the deformity will either be made worse or perfected by this exercise. If it be made worse it is due to the fact that the superincumbent body-weight is placed too much on the outer side of the tarsus, and that therefore every step the patient takes tends to emphasise the varus. One can see how deleteriously walking would affect such a case. Walking should give the finishing touches to the surgeon's art and should not be allowed until the body-weight at every step tends to flatten the plantar arch.

The effect of lengthened muscles opposed to deformity is very obvious, and when one realises the fact that in every case of club-foot the peronei and dorsi-flexors of the ankle have for months remained in a stretched condition, while the tibials and calf muscles are short and unstretched, it is easy to understand the imperfect recovery where no attention is paid to the strengthening of the weak group of muscles. The dorsi-flexors of the ankle and the peronei, which have for so long remained overstretched, behave to all intents as paralysed muscles would, and gravity decides the issue exactly as it does in the case of an equino-varus due to poliomyelitis. When the patient has arrived at the stage for walking and the deformity is corrected and, most important of all, when he can voluntarily evert and flex his foot, he should be taught to walk. Correct deflection of body-weight on the tarsus must, however, be assured.

If treatment is correctly carried out there is no apparatus required during after-care. The child should walk with an ordinary shoe with a flat heel. The so-called "orthopædic" shoes are a relic of the past. Massage of the peronei and the dorsiflexors should be continued and every device employed to secure voluntary action of these muscles.

"INSULIN" AND DIABETES:

THE PRESENT POSITION.

BY HENRY F. MOORE, M.D., D.Sc., N.U.I.,

VISITING PHYSICIAN, MATER MISERICORDIÆ HOSPITAL; AND
CONSULTING PHYSICIAN, COOMBE MATERNITY HOSPITAL,
DUBLIN; LATE ASSISTANT, THE HOSPITAL OF THE
ROCKEFELLER INSTITUTE FOR MEDICAL
RESEARCH, NEW YORK.

Dr. F. G. Banting, in November, 1920, conceived the ideas that: (a) since the acinous but not the islet tissue of the pancreas degenerates after ligation of the duct of the organ, advantage might be taken of this fact to prepare an active extract of islet tissue; and (b) trypsinogen or its derivatives destroy or are antagonistic to the internal secretion of the gland.

Experimental Basis.

Prof. J. J. R. Macleod, of the University of Toronto, gave facilities for and direction to the working of these hypotheses by Banting and Best.¹ The experimenters made extracts with Ringer's solution of dogs' pancreas after the acini had degenerated owing to previous ligation of the ducts or after they had been exhausted owing to repeated secretin injections and vagal stimulation below the diaphragm. The intravenous injection of these extracts into dogs rendered diabetic by pancreatectomy resulted in a marked fall in the percentage of sugar in the blood and abolition of glycosuria. The extracts obtained after previous ligation of the pancreatic ducts were the most potent for reduction of blood-sugar and the least toxic. In one dog the normal blood-sugar of 0.090 per cent. became 0.26 per cent. after pancreatectomy, and 3.10 g. of sugar were excreted in the urine during 24 hours; 5 c.cm. of potent pancreatic extract given intravenously resulted in the blood-sugar dropping from 0.26 per cent. to 0.16 per cent. in one hour; from the third hour after the injection the blood-sugar gradually rose again to 0.25 per cent. at the seventh hour when the injection of another 5 c.cm. of extract brought the sugar down to 0.18 per cent. Later injections brought the blood-sugar from 0.43 per cent. to normal, whilst extract of spleen or boiled extract of pancreas were impotent in this respect. Potent extract given per rectum or intravenous injection of extract on which active pancreatic juice was allowed to act were impotent. Extracts of glands in which the acini were not completely degenerated were more or less toxic on injection. The investigators make the following statement:—

"In the course of our experiments we have administered over 75 doses of extract from degenerated pancreatic tissue to ten different diabetic animals. Since the extract has always produced a reduction of the percentage of sugar of the blood and of the sugar excreted in the urine, we feel justified in stating that this extract contains the internal secretion of the pancreas."

The general conclusions from the foregoing experimental work are as follow:—

Intravenous injections of extract from dog's pancreas, removed from seven to ten weeks after ligation of the ducts, invariably exercise a reducing influence upon the percentage of sugar of the blood and the amount of sugar excreted in the urine.

Rectal injections are not effective.

The extent and duration of the reduction varies directly with the amount of extract injected.

Pancreatic juice destroys the active principle of the extract.

That the reducing action is not a dilution phenomenon is indicated by the following facts: (a) hemoglobin estimations before and after administration of extract are identical; (b) injections of large quantities of saline do not affect the blood-sugar; (c) similar quantities of extracts of other tissues do not cause a reduction of blood-sugar.

Extract prepared in neutral saline and kept in cold storage retains its potency for at least seven days.

Boiled extract has no effect on the reduction of blood-sugar.

In November, 1921, Banting and Best² discovered that the foetal calf pancreas of under five months' development did not contain (external) pancreatic juice, but did contain the internal secretion capable of reducing blood-sugar. They give an example of potency as follows: 50 g. of foetal pancreas were macerated in 250 c.cm. saline and filtered; 15 c.cm. of the filtrate were diluted to 250 c.cm.; a 15 c.cm. dose of this solution reduced the blood-sugar of a 10 kg. diabetic dog from 0.4 per cent. to 0.15 per cent. in three hours. It was found at this time that subcutaneous injection resulted in a slower and more prolonged but no less marked hypoglycæmogenic effect. It was also found that 0.7 per cent. tricesol added to the extract did not interfere with its action, but that by filtering through a Berkefeld candle much potency was lost. Alcohol was next tried as an abstractive in the endeavour to procure a sterile extract, and the active principle of the internal secretion was found to be alcohol soluble while the digestive ferments were not. For example, after macerating whole beef pancreas in 95 per cent. alcohol for 12 hours and filtering, the resinous-like residue obtained, after evaporating to dryness, when re-dissolved in saline and injected intravenously in suitable dosage, reduced blood-sugar in a dog from 0.35 to 0.08 per cent. in three hours, and rendered the urine sugar-free. The aid of Prof. Collip, of Edmonton University, was then invoked in order to prepare a protein-free extract and so avoid the depressor and reaction effects of the crude extract: this was accomplished successfully so that the extract could be studied clinically.

By the use of these extracts three *totally* pancreatectomised dogs lived 19, 21, and 70 days respectively. The injection of extract of other organs,³ such as spleen, liver, thymus, muscle, had little or no effect on blood-sugar, and that of thyroid had very little. Finally, an increase of the respiratory quotient almost to unity was observed in totally depancreatized dogs, showing the ability of the organism to utilise sugar after injection of the extract.

The next step was the trial of the extract, as now perfected, in the treatment of human diabetes.⁴ The investigators write:—

"The effects observed in depancreatized animals have been paralleled in man. The fall in blood-sugar occurs, and in two cases, repeatedly examined, a rise in the respiratory quotient indicating carbohydrate utilisation occurs more or less coincidentally with the attainment of a normal blood-sugar level. Patients report a complete relief from the subjective symptoms of the disease. The sugar excretion shows marked decrease, or if dosage be adequate, disappears. Ketouria is abolished, thus confirming a similar observation by Collip in diabetic animals. These results taken together have been such as to leave no doubt that in these extracts we have a therapeutic measure of unquestionable value in the treatment of certain phases of the disease in man. In agreement with observations of other investigators on laboratory animals, it has been found that without careful control severe toxic reactions may be encountered, and this will undoubtedly be a factor in the evaluation of the ultimate therapeutic utility of the method."

They give in this paper several clinical examples, including one boy in whom acidosis was also controlled in addition to glycosuria by treatment with the extract.

Preparation and Standardisation of Extract.

The method of preparation of the first extracts used clinically, devised for removing protein, salts, and lipoids and proteolytic ferments, was described by Collip⁵: fresh pancreas was macerated in an equal volume of 95 per cent. ethyl alcohol for several hours and filtered, two volumes of 95 per cent. alcohol were added to the filtrate, and the mixture was allowed to stand several hours to precipitate the major part of the proteins, filtered, and the filtrate which contained the active principle was evaporated at 10° to 30° C. in vacuo to a small volume. An aqueous extract was then made which was washed in a separatory funnel with ether to remove lipoids and distilled in vacuo to a thick consistence. 80 per cent. alcohol was added, and the whole centrifuged—the top clear layer of alcohol contains the entire active principles

in solution, below this were a flocculent layer of protein, a watery layer of saturated salt solution, and a lowermost layer of salt crystals. The top layer was removed, delivered into several volumes of 95 per cent., or better, of absolute alcohol, and the whole allowed to stand several hours until the active principle precipitated out. The latter was caught on a Buchner funnel, dissolved in distilled water, concentrated by vacuum distillation, filtered through porcelain, tested for sterility and delivered to the clinic. The final product was given hypodermically without any local reaction. Present methods of production are somewhat modified; with improved methods 5 kg. of beef pancreas yield about 200 to 400 units of insulin.

It now became necessary to devise some method of standardisation of the extract in order to regulate dosage. The name "insulin" was given to the extract by its discoverers. The unit of insulin was taken as the amount (in cubic centimeters) of the extract which on subcutaneous injection into normal fasting rabbits of 2 kg. weight caused a lowering of the blood-sugar to 0.045 per cent. (about 50 per cent.) in from one to three hours.⁶ In other communications it was shown that the injection of insulin in diabetic men and dogs raises the respiratory quotient when carbohydrate is fed, showing carbohydrate utilisation, and in diabetic dogs causes fat to be reduced in the liver at the same time that *glycogen accumulates* therein. It also abolishes the acetoneuria in diabetic dogs. Insulin added to the perfusing Locke's solution of excised surviving rabbit heart increases the glucose consumption more than thrice.⁷ If the blood-sugar of normal rabbits falls too low after injection of insulin, characteristic symptoms appear,⁸ such as hyper-excitability, fear, hunger, thirst, and finally clonic convulsions; as a rule, the convulsions appear when the blood-sugar falls to 0.045 per cent. These symptoms are completely abolished in a few minutes by subcutaneous or intravenous glucose injections, and are due to hypoglycæmia.

Macleod, discussing some of the experimental work,⁹ says that the function that is primarily regulated and controlled by the internal secretion of the pancreas is that concerned with the *deposition of glycogen*. The results obtained "seem to suggest that glycogen must be an essential preliminary stage in the utilisation of sugar by the animal body, and that when the pancreatic hormone is absent excess of sugar leads to the mobilisation of large quantities of fat." In discussing the matter he says:—

"In the light of these various types of evidence we feel justified in expressing the belief that it will be possible by administration of pancreatic extract to treat diabetes in man much more satisfactorily than has hitherto been the case. Dietetic control must no doubt remain an important feature of treatment, and will probably be all that is necessary in the earlier stages of the disease, but in the later stages it is hoped that administration of extract will prove of value. What other therapeutic uses the pancreatic extract may have remain as yet undetermined."

Clinical Study in Man.

Insulin has been distributed in Canada, U.S.A., and Great Britain to selected physicians and research workers for accurate investigation and study in the treatment of human diabetes. For example, over 50 cases were tested and observed in Toronto by Banting, Campbell, and Fletcher,¹⁰ and some of them were under treatment continuously for several months; many of them were severe cases.

"On the first or second day of treatment, if sufficient insulin is given, the urine becomes sugar-free, and on the second or third day ketone-free. These patients become conscious of increasing strength before the end of the first week. From a state which may be one of discouragement or of profound mental depression they become cheerful and interested. Hunger is replaced by appetite; the thirst is lessened; oedema, which is common in these cases, disappears. Patients find they are less irritable, and state that they begin to sleep well. The expression improves; the skin becomes less harsh and dry; even the hair becomes softer; in fact, the patient loses that appearance which characterises the diabetic. In ten days a very considerable amount of physical vigour is restored. Some patients have been able

to return to work after a month of treatment. The patient's weight frequently increases, and this can be readily brought about by supplying food in excess of the calorie requirement and increased amounts of insulin."

No case of diabetes was encountered which was not rendered aglycosuric *in spite of a large increase in the total calories*. Similarly, and perhaps more remarkable, the disordered fat-metabolism is restored to normal, inasmuch as insulin treatment results in rapid abolition of acidosis as evidenced by restoration of the normal alkali reserve of the blood, as well as by disappearance of ketone bodies from the urine and the signs and symptoms of this condition. Of ten cases of diabetic coma, six recovered—of the four fatal cases, two were inadequately treated with insulin; one died of pneumonia; one of vaso-motor failure and one of sloughing gangrene of the foot, and both these with sugar- and ketone-free urines and normal blood-sugars. Toxic reactions are rare, and dosage must be controlled by blood-sugar estimations, for, as in animals, also in man, when the blood-sugar percentage falls considerably (to 0.07 per cent.) under the influence of insulin, symptoms appear, such as nervousness, hunger, sense of weakness or fatigue or emotional instability; vaso-motor phenomena such as pallor or flushing and sweating are common. If the blood-sugar falls still lower there is acute distress or even mental disturbances, and, finally, coma, hypotonia, and loss of the deep reflexes. These symptoms can be relieved by carbohydrate administration, such as 50 to 100 c.cm. of orange-juice, or 5 to 25 g. of glucose with orange-juice by mouth or glucose injected intravenously or subcutaneously. One c.cm. of 1 in 1000 adrenalin intramuscularly is useful.

Clinical study of the hypodermic use of insulin in the treatment of diabetes mellitus in man therefore shows that: (a) Glycosuria is abolished; (b) blood-sugar is reduced and maintained at normal levels; (c) ketones disappear from blood and urine and acidosis is abolished; (d) the respiratory quotient shows increase in carbohydrate utilisation; (e) the chief symptoms of diabetes mellitus are relieved and the patients show marked clinical improvement; (f) insulin is practically a specific remedy for diabetic coma. The above results have been confirmed by some private communications to the present writer from reliable workers.

According to Collip⁵ the probable causation of the convulsive state in normal rabbits rendered hypoglycæmic by overdose of insulin is as follows: the glycogen-forming activity of the injected insulin lowers the sugar tension in the blood to such a degree as to jeopardise the oxidation of glucose in the tissues even though a certain amount of sugar still exists in the blood. This theory is supported by the fact that blood and urine of rabbit obtained immediately following the convulsive state shows qualitative and quantitative evidences of acidosis. It is well known that the oxidation of insufficient carbohydrate in the body will give rise to the formation of the so-called ketone bodies.

"These findings are of the greatest interest in that it would appear that while we have in insulin a substance which will correct all the acidotic signs, both in experimental animals rendered diabetic and in patients suffering from diabetes (if the dosage is adequate), it will, nevertheless, produce many of the cardinal symptoms of acidosis when administered to the normal animal in amount sufficient to produce a hypoglycæmia of a marked degree."

Some Properties of Insulin.

Insulin is apparently not a protein; it may be heated on a boiling water-bath for ten minutes in a faintly acid solution (pH 5 to 6) without appreciable reduction in strength, but actual boiling destroys it in three minutes; it is absorbed by kaolin and charcoal; its potency is greatly reduced by Berkefeld filtration.¹¹ Insulin is a white powder, soluble in water (except at pH about 5 or 6), giving a lævo-rotatory solution, and in alcohol (except at its iso-electric point).¹² Perfusion of the pancreas extracts the anti-diabetic substance in sufficient concentration to affect favourably on injection of the

perfusate all the major symptoms of diabetes produced in animals by depancreatisation.¹³

General Considerations.

The product must be given by subcutaneous or intravenous injection, as it is destroyed by trypsin; the dosage varies with the case according to the severity of the disease, the body weight, the diet, and so on. The dosage must be controlled by frequent blood-sugar estimations in each case, until one learns the amount in a given case on a given diet necessary to keep the fasting blood-sugar normal and to abolish glycosuria permanently. The usual plan of dosage is to divide the daily quantity into three equal parts, each part to be given just before the three chief meals. Anything from 6 to 50 rabbit units a day may be required, and some coma cases may require 150 units within 12 hours. Adjustments in doses are often necessary, because a dosage which just controls glycosuria one day may be excessive or inadequate on another.

Insulin is at present on the market in U.S. America, where its price is about 3d. per rabbit unit; the supply is very limited; it is expected that it will be offered by British producers of biological products in the near future; the cost and the frequent subcutaneous injections necessary over a long period of time are certainly disadvantages in the use of insulin. The consensus of opinion is, very definitely, that the insulin treatment of diabetes mellitus will not replace the dietetic treatment but will be an important adjunct thereto—at least in the severer cases. Probably, as heretofore, the less severe cases will not need the product at all, and we will, especially in non-juvenile cases, be able to control the disease by dietetic means alone. Its use, however, in the severe, the juvenile, and coma cases, as well as those complicated by severe acidosis, infection, and gangrene, will assuredly be a very great addition to our present methods of treatment. It is questionable whether insulin should be used at all except by those who can regulate its use by blood-sugar estimations, or in threatened or actual coma or gangrene; even then the danger of hypoglycaemia should be understood, and suitable measures should be ready for dealing with the characteristic symptoms.

In order to prevent improper use and commercial exploitation of insulin, the investigators applied for patents for their product in Canada, U.S.A., and Great Britain, and tendered the patents when granted to the University of Toronto in Canada and the Medical Research Council in Great Britain. I believe both these bodies will licence approved manufacturers to produce insulin under the patents, subject to the producers satisfying these bodies that the insulin produced is of adequate purity and potency. The original investigators receive no monetary return from the sales. In the meantime several laboratories and commercial houses are investigating the problems of producing the substance in large quantity, and certain physicians conducting clinics in large hospitals are studying the use of the product under controlled conditions. Recently Macleod¹⁴ has found that potent insulin preparations can be readily and comparatively inexpensively made from the principal islets of two readily available fish—namely, the angler (*Lophius piscatorius*) and the sculpin (*Myoxocephalus octodecimspinosus* and *scorpin*). In the majority of teleostean fishes the islet tissue is more or less separate from the zymogenous. It is collected into one or several easily recognisable nodules, often encapsulated and associated with relatively little, if any, zymogenous cells. From these islets extremely potent insulin preparations were made, requiring the use of comparatively little alcohol. For example, in one experiment, from 0.68 g. of dried islet tissue of the sculpin more than 12 rabbit units of insulin were obtained; in another case, 0.19 g. of dried islet of lophius gave more than 1 rabbit unit of insulin. It seems, then, that here is a cheaper and more readily available source of insulin than bovine pancreas, but whether this source can be practically used for large scale production is doubtful. If now a

method could be devised for giving the substance by mouth, the ideal in treatment would be attained.

It has for some time been known that pancreatic extracts have anti-diabetic properties on injection,^{15 16} as evidenced by abolition of acidosis, glycosuria, or hyperglycaemia. These extracts have never come into active use owing to uncertainty of action, and toxicity due to the contained ferments and proteins on injection. The literature contains many similar claims for pancreatic extracts given by mouth; in all such cases, however, the effects were too uncertain to be of much use clinically; the beneficent effects occasionally observed may be genuine, and if so encourage one to hope that a way may be yet found for administering insulin orally. Efficiency claims must, however, be substantiated by blood-sugar estimations which, in the majority of instances, were not done in these cases. What the Toronto workers have done is to isolate the active internal secretion of the pancreas from proteins, salts, lipoids, and external pancreatic ferments, so that its physiological effects could be accurately and scientifically studied and used, for the first time with success, in the treatment of diabetes mellitus.

My personal experience with insulin in the treatment of diabetes mellitus is brief and confined only to two cases, owing to the difficulty of obtaining the substance. In one case, an elderly man with gangrene of the foot, 25 units of insulin subcutaneously reduced the fasting blood-sugar (revised Folin and Wu method) from 0.181 to 0.070 per cent. in 2 hours and 20 minutes, and abolished a moderate glycosuria. In another case, a young woman, subcutaneous injection of 16 units reduced the blood-sugar from 0.216 to 0.117 per cent. in 1½ hours, and abolished a heavy glycosuria. The glycosuria and hyperglycaemia recurred in both cases on cessation of insulin administration, for no more of the product was obtainable at the time.

CRIMINAL RESPONSIBILITY.

REPORT BY A COMMITTEE OF THE MEDICO-PSYCHOLOGICAL ASSOCIATION.

THE Medico-Psychological Association of Great Britain and Ireland has submitted a report, drawn up by a special committee on criminal responsibility, to Lord Justice Atkin's Committee, who are considering whether any changes should be made in the existing law, practice, and procedure relating to criminal trials in which the plea of insanity as a defence is raised.

The medical profession, the report runs, are equally concerned with the legal profession and the public generally to ensure that the defence of insanity is not abused; they feel, however, that the law as at present interpreted is unsatisfactory, and does not always permit the best and fullest evidence of a prisoner's mental condition to be laid before the Court and Jury.

The M'Naughton Rules.

The Rules in M'Naughton's case have for many years been the subject of cogent criticism, both by medical men and by jurists.¹ That they have nevertheless retained their place in law to the present time has probably been due to (1) the failure to propound an acceptable alternative; (2) the fact that on numerous occasions individual judges have disregarded and declined to act on them; and (3) the knowledge, shared by judges and juries alike, that although a prisoner may be found guilty and sentenced, his case will be carefully reconsidered by experts appointed by the Secretary of State, in accordance with the Criminal Lunatics Act, 1884, and action will be taken accordingly, notwithstanding the finding of the Court.

As regards the Rules themselves, the report proceeds, we are aware that the Committee of this Association appointed to consider the matter in 1896 reported that they were unable at that time to make any suggestions for amending the law; but while fully conscious of the difficulty of the problem, we cannot agree that it is insoluble. We think that changes can be devised, which, without doing any violence to legal principles, would bring the law into closer accord with modern medical knowledge and requirements.

Criticism of Particular Rules.

We desire in the first place to offer some criticism of the particular Rules.

The Answers to Questions 2 and 3.—We take particular exception to the precise tests of responsibility laid down in the following words: "To establish a defence on the ground of insanity, it must be clearly proved that, at the time of the committing of the act, the party accused was labouring under such a defect of reason from disease of the mind, as not to know the nature and quality of the act he was doing, or, if he did know it, that he did not know he was doing what was wrong." Insanity is admittedly incapable of precise definition. The definition of a lunatic in the Lunacy Act, 1890, as "an idiot or person of unsound mind," although open to criticism, connotes defect or derangement of mind, and so may be accepted as a rough and ready criterion. Whatever may be the exact words used to describe the mental state of a person accused of crime, the law is only concerned to know whether it is a condition that negatives the existence of *mens rea*.

The legal principle involved creates a difficulty which is inherent in the problem of the criminal responsibility of the insane, and would have to be faced even if the M'Naughton Rules were abrogated. For these Rules are not wrong in holding that irresponsibility is only an inference that may or may not be drawn from insanity; where they err is in attempting to define precisely the conditions under which the inference is legitimate. They identify responsibility with knowing and reasoning, whereas any medical man with experience of the insane must know of many persons as to whose insanity (and irresponsibility) there can be no possible doubt, who have realised the nature and quality of their act, have known that it was contrary to the law, human and divine, and have shown remarkable cleverness in carrying out their object.

The Answers to Questions 1 and 4.—These may be dealt with together, as they both presume a condition of insane delusion in respect of one or more subjects or persons, or as to existing facts in persons who, it is suggested, are not in other respects insane. We submit that these answers are based on distinctions which, in the light of the present knowledge of mental disease, are out of date. In our view all insane delusions are indicative and symptomatic of general unsoundness of mind. The evidence of their existence will be most material in assisting the jury to decide whether the prisoner is in fact insane, and whether in view of his insanity he ought or ought not to be held answerable in law for his act.

The Answer to Question 5.—This answer relates only to the admissibility of the evidence of a medical man conversant with the "disease of insanity," who never saw the prisoner previously to the trial, but who was present during the whole

trial and the examination of all the witnesses. The value of the opinion of such an expert depends on its intrinsic worth.

Presentation of the Medical View.

We desire, however, to make it clear that in our opinion the real objection to the M'Naughton Rules involves something more radical than criticism of the terms in which they have been framed.

1. Even a slender acquaintance with the details of criminal cases in which medical evidence has seemed to fail to give the guidance to the Court that it was intended to provide, reveals the fact that some definite change in the medical view as to what constitutes insanity has occurred since 1843, when, it must be assumed, the judges framed the M'Naughton Rules in accordance with what they were advised was the generally accepted medical view as to the nature of insanity. Doubtless it was thought that medical men would find no serious practical difficulty in answering the supposed questions. Such an accommodation is now impossible, because it implies a conception of unsoundness of mind that is obsolete. Unsoundness of mind is no longer regarded as in essence a disorder of the intellectual or cognitive faculties. The modern view is that it is something much more profoundly related to the whole organism—a morbid change in the emotional and instinctive activities, with or without intellectual derangement. Long before a patient manifests delusions or other signs of obvious insanity he may suffer from purely subjective symptoms, which are now recognised to be no less valid and of no less importance in the clinical picture of what constitutes unsoundness of mind than the more palpable and manifest signs of the fully developed disorder, which may take the form of delusions, mania, melancholia, or dementia.

The practical bearing of this is twofold: first, it shows how it has come about that present-day medical witnesses find a real difficulty in satisfying the Court when pressed to give a categorical Yes or No to the M'Naughton questions as framed; and second, it shows the impracticability of attempting to frame any other formula. On this basis, therefore, it is thought to be a reasonable proposition to say, Let the facts as to insanity be put before the Court unhampered by any formula. Elucidation of all the relevant facts, including such conditions of defective control as occasion epilepsy, impulses, obsessions, hysterical states, drug addiction, and alcoholism in their bearing upon an alleged crime, would, in many cases, be necessary, and medical witnesses experienced in the care and treatment of the insane could give assistance to the Court in that direction. A jury, upon the facts so presented, with such guidance as the judge might feel it necessary to give, should have no insuperable difficulty in reaching a correct conclusion.

2. In our view the Law should be framed so as to allow the medical witness alleging insanity to make it clear that the facts observed by himself, supplemented by other evidence before the Court, form in his mind a coherent clinical picture of mental disorder; and he should be in a position to state that the prisoner's criminal act is symptomatic of, or at least consistent with, such a condition. His evidence should enable a jury to find that, even if there should be no apparent logical connexion between the prisoner's mental derangement and his criminal act, it is reasonable to conclude that both form part of his mental unsoundness, and it is important that that evidence should be placed before them as fully as possible. According to the present practice, experts on this question are subject to restrictions which are not imposed on experts on other matters. There does not appear to be any sufficient reason why a medical man should not be allowed to state his grounds for arriving at an opinion in his own way, subject always to the fullest cross-examination by the other side and by the Court.

3. We see no reason why a medical witness who has not examined the prisoner should not be asked "hypothetical" questions.

Abandonment of a Legal Criterion.

It may be objected to the foregoing observations that they imply the abandonment of a legal criterion of responsibility, and that such a criterion is indispensable. In this connexion it may be useful to refer to the practice at present prevailing in Scotland.

By Scots Law, as by the Law of England, insanity is a good defence only in so far as it negatives the existence of *mens rea*, and the Rules in M'Naughton's case were for some time quoted with approval by judges as expressing the law of Scotland no less than that of England. (Gibson, 2 Broun 332, and Smith and Campbell, 2 Irvine 1—per Hope, Lord Justice-Clerk.) But they do not now appear to be considered in Scotland. The present state of Scots Law in regard to insanity as a plea or defence is thus expressed by Lord Duncannan, Lord Justice-General, in *H.M. Advocate v. Brown* (1907 S.C. (J) 67 at p. 76):—

"In one sense no one can say what insanity is. I do not think if we had all the doctors here who are learned on the subject that any two of them would agree on a definition. It is quite certain that what may be called the scientific view on

¹ The questions put to the 15 judges by the House of Lords after M'Naughton's acquittal were as follows:—

Question 1.—What is the law respecting alleged crimes committed by persons afflicted with insane delusions in respect of one or more particular subjects or persons, as, for instance, where, at the time of the commission of the alleged crime, the accused knew he was acting contrary to law, but did the act complained of with a view, under the influence of insane delusion, of redressing or revenging some supposed grievance or injury or of producing some supposed public benefit?

Question 2.—What are the proper questions to be submitted to the jury when a person, afflicted with insane delusions respecting one or more particular subjects or persons, is charged with the commission of a crime (murder, for instance) and insanity is set up as a defence?

Question 3.—In what terms ought the question to be left to the jury as to the prisoner's state of mind at the time when the act was committed?

Question 4.—If a person under an insane delusion as to existing facts commits an offence in consequence thereof, is he thereby excused?

insanity has greatly altered in recent years, and Courts of Law, which are bound to follow, so far as they can, the discoveries of science and results of experience, have altered their definitions and rules along with the experts. . . . Acts of Parliament cannot deal with scientific opinions, and therefore it is left to juries to come to a common-sense determination on the matter, assisted by the evidence led and any direction which the judge can give."

Reference may also be made to the direction of Lord Moncreiff, Lord Justice-Clerk, in *H.M. Advocate v. Miller* (1874, 3 Coup. 16).

Conclusions.

In accordance with the views expressed above we have come to the following conclusions:—

1. The legal criteria of responsibility expressed in the Rules in *M'Naughton's* case should be abrogated, and the responsibility of a prisoner should be left as a question of fact to be determined by the jury on the merits of the particular case.

2. In every trial in which the prisoner's mental condition is in issue, the Judge should direct the jury to answer the following questions: (a) Did the prisoner commit the act alleged? (b) if he did, was he at the time insane? (c) if he was insane, has it nevertheless been proved to the satisfaction of the jury that his crime was unrelated to his mental disorder?

3. We would further suggest that the present practice of dealing with persons who are found insane upon arraignment is unsatisfactory and might be reconsidered. As the law stands a finding of insanity upon arraignment may result in a man—conceivably unconnected with and innocent of the offence with which he is charged—being sent to a criminal lunatic asylum. Experience shows that it is always best, if possible, to let the prisoner stand his trial and plead. This course does away with his after grievance that he was never convicted of the offence with which he was charged, and that in fact he never was tried for it. In the vast majority of cases there is no reason to doubt that the man did commit the act, but the fact that the crime was never brought home to him, and that, being found insane, he has been ordered to be detained during His Majesty's pleasure, does give him a grievance of which he makes the utmost use, and to which it is difficult to give a satisfactory answer. When a person is found unfit to plead we would suggest that a plea of "Not Guilty" should be recorded by the Court and the trial on the facts allowed to proceed—in his absence if he cannot properly be present in Court, arrangements being made for him to be represented by counsel and solicitor. We presume that to enable this course to be adopted some amendment of the Criminal Lunatics Act, 1800 (39 and 40 Geo. III., c. 94), Sec. 2, would be necessary.

4. We would also suggest that the law be amended to enable the verdict now expressed as *Guilty but insane* to rank as a conviction for the purposes of appeal to the Court of Criminal Appeal.

5. We are of opinion that it would not be practicable to have medical assessors to the Court in cases where insanity is raised as a defence to a criminal charge. We think, however, it might be possible to have a panel of accredited experts appointed, any of whom could be called on by the Court to give evidence, subject to cross-examination by either side, and without any derogation from the right of either side to call its own expert witnesses.

The report, which is signed by Dr. Nathan Raw (Chairman), Dr. R. Worth (Hon. Gen. Sec.), and Prof. G. M. Robertson (President), concludes with the remark: "We do not favour any amendment of the Criminal Lunatics Act, 1884, the provisions of which are both humane and necessary."

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

A New Anæsthetic Gas.

MUCH interest has been excited by a demonstration of the anæsthetic properties of ethylene, carried out in the physiology department of Chicago University. The attention of Dr. A. B. Luckhardt and Mr. J. B. Carter was directed to this gas by the discovery that carnations in Chicago greenhouses showed a most undue tendency to somnolence. The botanical department having identified the ethylene content of the illuminating gas as the chief culprit, the physiological department determined to study its effects on animals. Frogs, mice, rats, rabbits, guinea-pigs, and kittens were all anæsthetised with a mixture of 90 parts C_2H_4 and 10 parts O_2 in one-half the time necessary to anæsthetise the same animals with the

same proportion of nitrous oxide. Experimenting next with the dog they showed that deep anæsthesia could be maintained for as long as 15 minutes, that there was no effect on blood pressure, and that recovery on ceasing to administer the gas was always rapid and complete. Finally, the two experimenters anæsthetised each other and a number of volunteers, their experience being that induction of anæsthesia by this method is not unpleasant and leaves no after-effects beyond temporary ataxia and some feeling of nausea.

"Hygeia."

The contents page of the first number of *Hygeia*, to be published in April, suggests a very readable little journal. Dr. Victor C. Vaughan writes on Pasteur and his work: Dr. Woglom asks, Does Meat Cause Cancer? while Dr. Arthur J. Cramp, who has for years done admirable work in charge of the propaganda department of the American Medical Association, begins a series of articles on patent medicines. Besides several more signed articles there will be 20 pages devoted to short paragraphs under various seductive titles, such as Plain Facts about Health and Disease, Around the Clock with Baby, and Simple Simon and the Doctor. The making of health propaganda attractive to the general public, so that they will be willing to pay for it, and therefore possibly even to read it, is an experiment worth watching.

Sensations for the Credulous.

The leading daily papers have recently given a considerable amount of space to reports from Escanaba, Mich., of a girl who persisted in living, remaining conscious, and desirous of getting up and going for a walk with a temperature of $114^{\circ}F$. The old hot-water bottle trick (for such it eventually proved) can rarely have met with such astounding success in the history of malingering. At the same time it is announced that Dr. Abrams, who by his remarkable technique should be able to tell from a drop of dried blood the nicer shades of the patient's religious faith, has now discovered that his "sphygmobiometer" can detect the presence of water, oil, and minerals, and even their quantity and the depth at which they will be found. If clients are paying to be told on the evidence that they have syphilis or tuberculosis, the claims of the inventor should be given a thorough scrutiny and the results published.

Illicit Alcohol.

The incautious have paid recently a heavy toll through the consumption of illicit alcohol. A full dozen middle Western States have Bills before them for the stricter enforcement of prohibition. In Kansas the proposed legislation would qualify as murder the selling or giving away of "intoxicants that cause death." In Oklahoma this crime is already punished with the murder penalty; in Iowa and Michigan it is to be manslaughter; and in Ohio "second degree" murder.

March 17th.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Comdr. E. D. J. O'Malley is placed on the ret'd. list with the rank of Surg. Capt.

ROYAL ARMY MEDICAL CORPS.

The undermentioned Majors to be Lt.-Cols.: R. N. Hunt, vice Lt.-Col. R. F. Ellery, ret. pay; and Bt. Lt.-Col. E. Ryan to complete estab.

Capt. E. Catford and J. H. Pendered retire, receiving a gratuity, and are granted the rank of Maj.

Capt. D. W. Pailthorpe is ret'd. to the estab.

Temp. Capt. R. Murphy to be Lt.

TERRITORIAL ARMY.

Capt. J. B. Foubister (late R.A.M.C., T.F.) to be Capt.

Capt. H. L. Garson, J. S. Hudson, and J. Paton to be Maj. (prov.).

Capt. L. B. Cane to be Maj.

Capt. G. W. Deeping relinquishes his commn. and is granted the rank of Maj.; and Capt. R. T. Jones relinquishes his commn. and retains the rank of Capt.

Capt. W. P. Croker, R.A.M.C., to be Div. Adjt., 47th (2nd London) Div., T.A., and School of Instruction, vice Capt. J. H. Barry, R.A.M.C. vacated.

INDIAN MEDICAL SERVICE.

Capt. W. D. Keyworth to be Maj.

The King has approved the grading of the following officers, who have been granted permanent commissions since the outbreak of the war as follows: Capts. S. R. Prall and H. Williamson; and Lt. C. A. Kirton.

C. M. Nicol to be Capt. A. L. Watts to be Lt.

Maj. (actg. Lt.-Col.) D. C. V. Fitzgerald relinquishes his actg. rank on ceasing to comd. an Indian Central Hospital.

Capt. Amrita Nath Banerji relinquishes his temp. commn.

Lt.-Col. and Bt. Col. H. B. Fawcus, R.A.M.C., has been appointed Hon. Physician to the King, vice Maj.-Gen. Sir Alfred Blenkinsop (ret.).

Maj. T. J. Crean, R.A.M.C. (ret'd.), died at his residence in Mayfair on March 25th, aged 50.

The death is announced of Inspector General W. H. Lloyd, R.N., on April 2nd, at the age of 87. Inspector General Lloyd, who was honorary surgeon to the King, was the oldest officer of his rank in the Navy.

Obituary.

THOMAS JOSEPH CREAN, V.C., D.S.O.,

F.R.C.S. IREL.,

MAJOR, R.A.M.C. (RETD.).

Major Crean, who died at his residence in Queen-street, Mayfair, on March 25th, in his fiftieth year, was the son of Michael Theobald Crean, a barrister and a member of the Irish Land Commission. Thomas was born in Dublin, and received his early education at Clongowes College, afterwards studying medicine and qualifying L.R.C.P., L.R.C.S. Ireland in 1896. He was assistant master of the National Maternity Hospital in Dublin, went out to South Africa and entered on general practice at Boksburg, Transvaal, and when interrupted by the war in 1899 joined the Imperial Light Horse as a trooper. In 1901 he was appointed surgeon-captain in the regiment and was wounded at Elands-laagte and at Tygerskloof. It was during this latter action that he won the Victoria Cross, the official record stating that "During the action with De Wet at Tygerskloof on Dec. 18th, 1901, the officer continued to attend to the wounded in the firing line, under a heavy fire at only 150 yards range, after he had himself been wounded, and only desisted when he was hit a second time, as it was at first thought, mortally wounded." After the war he took up practice again, this time on the West Coast of Africa. When war broke out in 1914 he rejoined the army as a major in the R.A.M.C., and served with the 1st Cavalry Brigade, being mentioned in despatches and receiving the D.S.O. In 1916 he was appointed officer in command of the 44th Field Ambulance in France. On his return, broken in health but not in spirit, he became medical officer in charge of the hospital at the Royal Enclosure on the Ascot Race-course. In addition to the Victoria Cross his war honours included the Queen's Medal with five clasps and the King's Medal with two clasps. He also held the Royal Humane Society's Medal for saving life at sea and was awarded the Arnott Memorial Gold Medal in 1902. In the same year the Royal College of Surgeons in Ireland conferred upon him the honorary Fellowship. It is not surprising that a man of Crean's stamp should have also gained honours in the football field. He was a fine Rugby forward, a member of the Irish International XV. in 1894-96 and of the English team in South Africa in 1896. He married in 1905, Victoria, daughter of Señor Don Tomas Heredia, of Malaya, by whom he had one son and one daughter. Known always to his friends as "Tommy," Crean's death leaves a gap in the circle that will not be easy to fill. Generosity, discretion, and tact were his, and more important still, invincible cheerfulness and courage.

Correspondence.

"Audi alteram partem."

HERNIA IN GENERAL PRACTICE.

To the Editor of THE LANCET.

SIR,—As a general practitioner I wish to say how useful your articles on Modern Technique in Treatment are to me, and to hope that there will be more of them on the present lines. The article on the Treatment of Oblique Inguinal Hernia in Adults, in your issue of March 24th, is a good example; the young operator who may have seen many such operations is up against a very different proposition when he does his first radical cure. The text-books that generally say "the sac is easily recognisable, isolated, and cleaned . . ." are not much help to him, looking for it and trying not to feel rattled at not finding it at once. I notice that Prof. A. W. Sheen says "*the whole sac must be removed.*" Do not most surgeons leave the blind lower end of the sac, if there is any difficulty in removing it? Another small point, but most important for beginners, in my opinion, is that the external oblique fascia should be separated back from the underlying structures on each side after division, by the finger; the sutures joining Poupart's ligament to the muscle above the canal are then easily passed. My comments are perhaps superfluous, but I make them to emphasise the importance to us general practitioners of detailed information in these articles.

I am, Sir, yours faithfully,

L. P. GIBSON, M.R.C.S., L.R.C.P. Lond.

Cowes, I.W., March 25th, 1923.

* * We thank our correspondent for his generous appreciation. Experience in recognising the hernial sac can readily be obtained by assisting or even watching other people operate. After the cremasteric fascia has been divided, the cord should be pulled up and spread out over the middle finger. When this is done, the bluish white sac, with the convex edge, will be seen shining through the other coverings. It lies in front of the other structures of the cord. Prof. Sheen emphasises the fact that the ligation must occur right up at the neck of the sac, because if a small portion is left a recurrence is certain to take place. No harm may follow from leaving the lower part of the sac, though it is usual to remove it. It is unnecessary to separate the external oblique far back from the underlying structures if the Johns Hopkins operation is carried out. In this the upper margin of the cut external oblique is brought down and sutured, with the lower margins of the internal oblique and transversalis muscles, to the upper surface of Poupart's ligament. The lower border of the external oblique is made to overlap the upper flap. Firm union will then take place between two broad surfaces. This procedure is probably followed by fewer recurrences than happen with any other.—ED. L.

ANNULAR SHADOWS IN THE RADIOGRAM.

To the Editor of THE LANCET.

SIR,—I read with great pleasure the article on the X ray examination of the chest by Dr. Bernard Hudson and Mr. P. G. Sutton in your issue of March 17th, but I quite agree with the views put forward by Dr. C. H. Brodribb in his letter in your following issue on annular shadows in the radiogram. I think it would be impossible that a cavity of sufficient size to be seen in an X ray photograph should give no physical signs, and, moreover, these annular shadows are seen so frequently at one time, and disappear at another, that it is evident they cannot be due to cavitation. I think it more likely that the shadow is due to an annular adhesion produced by a local pleurisy, which would explain the absence of physical signs.

L'AFFAIRE SPAHLINGER.

To the Editor of THE LANCET.

SIR.—I have only recently had the opportunity of reading in your issue of March 10th a letter from Dr. A. H. Croucher, who first applied Mr. Spahlinger's methods in England in 1913. I can claim an earlier association with this treatment, as I first became interested in it by controlling the experimental work. In 1912 I had the opportunity of using the vaccines on a human being. The patient suffered from lymphoma

siderable improvement until the want of serum stopped the treatment. Two of the patients, who were quite well and had resumed work in 1916, died of influenza during the 1918 epidemic, one died of another disease, five have been lost sight of. The remaining 12 patients have all been traced; they have now been at work for seven years, one of them being a bad case of bilateral tuberculosis of the kidneys complicated by tuberculosis of the spine.

In a report during October, 1915, I made this emphatic statement: "As long as a consumptive is

DR. EDMOND LARDY'S CASE OF LUPUS AND SUPPURATING LYMPHOMA TREATED WITH SPAHLINGER REMEDIES.

Condition in 1912.

After two injections.

After four injections.

After 12 injections.

of the neck (right and left sides) which were ulcerated and suppurating: on the manubrium sterni there was an ugly patch of lupus about 3 inches in diameter. The patient had been treated in two hospitals over periods of nine months and four months, but the disease had resisted all ordinary methods of treatment.

A complete recovery was effected after 16 injections of Spahlinger's vaccine. I consider it remarkable that eight tuberculous glands, all suppurating, as well as a large patch of lupus, could be made to disappear with so limited a treatment. Ever since her recovery, in 1912, this patient has lived in very poor and unfavourable conditions. Notwithstanding this, she has remained in perfect health all these years, all that is evident at present being a few scars under her chin. Of the accompanying photographs the first three were taken after two, four, and 12 injections respectively in 1912, and the other two show the patient's condition in 1923.

I was associated in the preliminary note presented to the Academy of Medicine at Paris in 1914 and I have delayed further publications in order to avoid increased demands for remedies which cannot yet be supplied. In view, however, of the present situation, I believe that my testimony may be of some value. After Mr. Spahlinger's return from England in October, 1914, I was able to treat 23 cases with partial sera, ferments, and vaccines. Most of these patients were in an acute or advanced state; other methods having failed to improve their condition, they might certainly have been considered as "incurable." As a result of the laboratory being closed during Mr. Spahlinger's absence in London, 1913-14, no remedies were produced during that period, and the supply of serum became exhausted early in 1915, thus stopping the treatment of 10 advanced cases. The entire vaccine supply became exhausted at the end of 1915.

Of the 23 cases treated by me, three subsequently died from tuberculosis, although they made con-

Condition in 1923.

living, no matter how far gone his case may be, he can be cured with the Spahlinger treatment, without being obliged to go to the mountains." Since that date the amount of clinical evidence over a long period goes to show that this statement was correct, and I consider that if the complete remedy had been available I should probably have saved all of my 23 cases—excepting, of course, those who died from diseases other than tuberculosis. It is important to note that the patients who went through the course of vaccines are alive to-day and carrying on their normal occupations.

I am, Sir, yours faithfully,

EDMOND LARDY.

ALCOHOL AND INSANITY.

To the Editor of THE LANCET.

SIR,—Dr. Stanley Wyard in THE LANCET of March 24th suggests that the reason why the virtual elimination of alcoholism during the war had no appreciable effect on the occurrence of insanity is to be found in the "greatly increased mental stress" which prevailed in that period. This increased mental stress, it would seem, took the place of alcoholism as a detrimental agency, and is thus assumed—for there is no evidence—to have been during the war years the chief factor in the causation of insanity.

This is a remarkable proposition, and I can hardly imagine that it corresponds to common belief or that it will command the "almost universal acceptance" Dr. Wyard anticipates. Most psychiatrists who have had experience in this special field of work—e.g., on pensions boards—seem to have arrived at very modest estimates of the effect of war stress in causing insanity, even in the case of the actual combatants. It would certainly be somewhat curious if this same influence were a factor of such great potency in producing insanity in the civil population.

SERUM DOSAGE IN DIPHTHERIA.

To the Editor of THE LANCET.

SIR,—I have read with much interest Dr. C. B. Ker's note on this subject in your issue of March 31st. He commends yet criticises the memorandum of the Ministry of Health. He considers that to administer 8000 units in any case is both safe and efficient, and while admitting that such a dose, or much larger ones, are often necessary, he does not consider 8000 units necessary in mild cases and regards such a minimum dose as likely to lead to waste of money.

I do not think anyone can disagree with his contention that there are cases which do not require such a dose, but unfortunately as a profession we are not all capable of selecting them. If Dr. Ker tells us a given case is mild we can thoroughly rely upon his opinion, for we know it comes from an expert who carefully weighs all the evidence, but can we so rely upon the opinion of those who are not experts? I say from much experience that we cannot do so. I know that it is not always a simple matter for me to tell at once with precision what the severity of the attack is or is going to be, and it must be more difficult for those of less experience; indeed, one knows this to be so. Amongst those who are inexperienced the tendency undoubtedly has been to give too small doses and to give the dose irrespective of the severity of the disease.

If a minimum dose of 8000 units is both safe and efficient and is applied in practice, then a great saving of child life will occur in the community and this will far outweigh in monetary value the added cost for the production of diphtheria antitoxin.

I am, Sir, yours faithfully,

FREDERIC THOMSON.
North-Eastern Hospital, Tottenham, N., March 31st, 1923.

BURIED RADIUM EMANATION TUBES.

To the Editor of THE LANCET.

SIR,—In an annotation on the Treatment by Radium in THE LANCET of March 10th the statement occurs: "But the American recognition of the possibility of burying small, unscreened glass tubes in tumours made possible the deep use of beta rays." Colwell and Russ in their book "Radium and X Rays and the Living Cell," published in 1915, state (p. 78): "Joly¹ and Stevenson² have succeeded in using the emanation when it is sealed in glass tubing so thin that it may be inserted in an ordinary hypodermic needle. Its insertion into growths thus becomes much simplified and the beta rays are largely utilised."

¹ Proc. Royal Dublin Society, May 8th, 1914.

² Brit. Med. Jour., July 4th, 1914.

And at the meeting of the British Medical Association, held in Aberdeen in 1914, the Dublin method was criticised as affording too little screening from beta rays. The point in the Dublin method is not only the utilisation of primary beta rays, but also the employment of a number of sources of these rays, by distributing several capillaries at one time in a tumour in order to obtain as uniform a radiation of a tumour as possible. These fine capillaries containing emanation were first made by Mr. R. J. Moss at the Royal Dublin Society Radium Institute in April, 1914, and similar tubes are now extensively used in America, where the Dublin work is recognised. I have occasionally buried bare capillaries in tumours and left them there, but the usual method in Dublin is to use 6 to 12 serum needles, each containing one of these capillaries and to withdraw them when a sufficient dose has been given. As the wall of the serum needles is only 0.3 mm. thick this is principally a beta ray method of treatment, and was originated in Dublin.—I am, Sir, yours faithfully,

WALTER C. STEVENSON,
Surgeon Orthopaedic and Dr. Steevens' Hospital, Dublin.
Dublin, March 26th, 1923.

THE OPERATIVE TREATMENT OF SEPTIC MENINGITIS.

To the Editor of THE LANCET.

SIR,—In reply to Mr. W. Stuart-Low's letter in your issue of March 31st I can only imagine that he must have misread both my original communication and that of Sir William Milligan. In the former it was clearly stated that Gram-positive diplococci were present in both the cerebro-spinal fluid and in the fluid withdrawn from the subarachnoid space of the posterior fossa. Even Sir William Milligan, keen exponent of the "serous" theory though he be, agrees from this fact that the case was undoubtedly one of "early and genuine septic meningitis." Mr. Stuart-Low gives no definition of his meaning of "serous" meningitis in quoting a mortality for it of 5 per cent., and as Mr. Edward Davis pointed out it would be difficult to correlate this percentage with Mygind's series of 133 fatal cases, in 70 per cent. of which the cerebro-spinal fluid was sterile.

The academic discussion as to the exact delimitation of serous from septic meningitis is, after all, of little import compared with successful means of dealing with cases where operation is decided upon, and if Mr. Stuart-Low's method of positive suction has produced three out of four successful cases it must obviously be of the greatest importance. It will be interesting to compare these results with Mr. G. J. Jenkins's series when it is published.

I am, Sir, yours faithfully,

Eton, March 29th, 1923. HENRY L. MARTYN.

LONDON PANEL COMMITTEE: HOLIDAY LOCUM SCHEME.

To the Editor of THE LANCET.

SIR,—The London Panel Committee in 1922 instituted a scheme whereby the employment of whole-time locum-tenents during the holiday season can be avoided. Under the scheme practitioners can by arranging themselves into groups of not less than five members, all living within a radius of one mile, undertake the care of the practice of one member whilst away on holiday. The working of this scheme in 1922 proved very satisfactory and quite economical. I shall be pleased to send full information as to the scheme to any practitioner, or group of practitioners, in London, who may be interested, and as the holiday season is drawing near I would ask that early application for particulars should be made.

I am, Sir, yours faithfully,

ROBERT J. FARMAN,
Secretary, Panel Committee for the County of London.
Staple House, 51, Chancery-lane, W.C. 2, March 27th.

* * * This excellent scheme was dealt with in a leading article in THE LANCET of May 6th, 1922.—ED. L.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

Dangerous Drugs and Poisons Bill.

THE Dangerous Drugs and Poisons (Amendment) Bill was considered by Standing Committee B of the House of Commons on Tuesday, March 27th. Mr. PONSONBY presided.

Mr. BRIDGEMAN (Home Secretary) moved the following amendment to Clause 2 of the Bill:—

"No proceedings for an indictable offence against this Act shall in England or Wales be instituted except by or with the consent of the Attorney-General or by the Director of Public Prosecutions, and no person shall, on conviction for any offence of contravening or failing to comply with any regulation under this Act relating to the keeping of books or the issuing or dispensing of prescriptions containing drugs to which this Act applies, be sentenced to imprisonment without the option of a fine or to pay a fine exceeding fifty pounds, if the court dealing with the case is satisfied that the offence was committed through inadvertence and was not preparatory to or committed in the course of or in connexion with the commission or intended commission of any other offence against this Act."

He explained that the amendment was the first of a series which he proposed to move in order to meet certain objections to the Bill which had been put forward by the medical profession and the Pharmaceutical Society.

The amendment was agreed to.

Mr. BRIDGEMAN moved a further amendment to Clause 2 to provide that where a person convicted of an offence under the Act was a company, the chairman and every director and every officer concerned in the management of the company should be guilty of a like offence unless he proved that the Act constituting the offence took place without his knowledge or consent.

The amendment was agreed to.

On Clause 3 Mr. BRIDGEMAN moved to leave out the words "in actual practice" after "registered medical practitioner" in Subsection (1) of the clause.

Mr. HAYDAY asked why the words were to be left out.

Sir S. RUSSELL-WELLS pointed out that the words "in actual practice" had an extremely technical significance in the medical world. Medical officers of health, for example, were not in actual practice.

Lieut.-Colonel FREMANTLE said that if his hon. friend was taken ill and these words were not taken out of the Bill they would not be able to prescribe for him in order to save his life.

The amendment was agreed to.

Mr. BRIDGEMAN moved a further amendment to Clause 3 as follows:—

"Provided that if a seller is reasonably satisfied that a registered medical practitioner desiring to purchase a poison urgently requires it for the purpose of his profession, but is, by reason of some emergency, unable, before delivery, either to furnish to the seller an order in writing duly signed, or to attend and sign the book, the seller may send the poison to the purchaser to be handed over to him either in exchange for such an order or on an undertaking by the purchaser to furnish such an order to the seller within the 24 hours next following. If any purchaser by whom any such undertaking as aforesaid has been given fails to deliver to the seller a signed order in accordance with the undertaking, or if any person for the purpose of obtaining delivery of any poison under the foregoing proviso makes a statement which is to his knowledge false, he shall be deemed to have procured the commission of an offence under the said Section 17."

The amendment was agreed to.

Mr. BRIDGEMAN moved the following new clause:—

(1) Where any poison to which Section 17 of The Pharmacy Act, 1868, applies is supplied on and in accordance with a written prescription given by a registered medical practitioner under and in accordance with the provisions of the Acts relating to national health insurance, the seller of the poison shall not be required to make any entry in the book in accordance with the requirements of the said section.

(2) The said Section 17 shall have effect as if for the words "labelled with the name of the article and the word poison, and with the name and address of the seller of the poison," there were substituted the words "labelled with the name and address of the seller of the poison, with the word 'poison,' and with the name of the poison, and, in the case of a preparation which contains a poison as one of the ingredients thereof, with such particulars as to the proportion which the poison contained in the preparation bears to the other ingredients as may be prescribed by Order in Council."

He said he understood the medical profession and the chemists were agreed upon the clause.

The clause was read a second time and agreed to.

Colonel FREMANTLE said that as chairman of the medical Members of the House of Commons he wished to say how much obliged they were to the Home Secretary for having met their points in regard to this Bill. Those points had been raised in the public interest and not to further professional interest. He thought it would be recognised by all

those who know the facts that two or three very long-standing difficulties had been removed by this Bill as amended, and at the same time they had helped and not hindered the policy of the Government in dealing with the dangerous drugs traffic.

Mr. SHINWELL said that British seamen touching such ports as Antwerp, Hamburg, or the Chinese or Japanese ports were often offered inducements to carry drugs to this country. The penalties imposed under the Bill were very drastic, and he asked the Home Secretary to give an assurance that notices would be placed in the fore-castle of British merchant vessels so that seamen might know the risks they ran if they engaged in this traffic.

Mr. BRIDGEMAN said that he thought that the matter raised by Mr. Shinwell was one which affected the administration of the Board of Trade, but he would represent to the Board of Trade that something should be done on the lines suggested by the hon. Member. He wished to reciprocate the remarks of Colonel Fremantle and to thank the medical Members of the House and the Pharmaceutical Society who had been good enough to meet him so fairly in this matter. It would be the last thing that he would wish to do to cast any slur or suspicions on those gentlemen, and he was glad that any idea of that kind had been removed. He was confident that the medical profession and the pharmacists would give him the support which would be of extreme value in putting down this horrible traffic.

The Bill passed through committee and was ordered to be reported with amendments to the House.

HOUSE OF LORDS.

TUESDAY, MARCH 27TH.

Certificates for Mentally Infirm Ex-officers.

Lord SANDHURST asked the Government whether it was a fact that ex-officers who were mentally incapacitated and for that reason were drawing disablement pensions were in addition to being examined from time to time by a pensions board required as a condition of payment of each instalment of pension to obtain a certificate of their mental infirmity not only from a magistrate or minister of religion but also at their own expense from a medical practitioner; and whether the requirement might not safely be dispensed with.

The Earl of MALMESBURY (Lord-in-Waiting), who replied on behalf of the Ministry of Pensions, said that the position to which the noble lord had drawn attention arose out of the provisions made under Section 335 of the Lunacy Act, 1890, for overcoming the legal difficulty of obtaining a valid receipt for moneys due to a person incapable of managing his own affairs. Those provisions were made for the protection of the pensioner himself as well as for the protection of the public funds. He believed that no charge for a certificate was ever made by medical officers in charge of approved mental institutions, and so far as he was aware no charge was made by the magistrates or ministers of religion. This procedure could not be departed from in the more serious cases, which were fortunately very rare, and Lord Malmesbury thought that Lord Sandhurst was unduly apprehensive on the point. The vast majority of the more serious cases were in approved institutions. In cases of a milder character it would be generally found possible to dispense with the procedure prescribed by the Lunacy Act and to proceed under the authority of a Treasury Warrant and to pay the pension on a certificate provided by one only of the prescribed attestors, who need not be a medical practitioner. This was a growing practice of the Ministry of Pensions, and it was their intention in the future to act even more fully under that system. Medical boards were held much less frequently than formerly and rarely more than once a year. In regard to the second part of the question, he did not think any medical certificate was required when the pension was paid to the pensioner himself.

While it was not quite relevant to the noble lord's question, Lord Malmesbury said he might be permitted to indicate the comprehensive measures adopted by the Ministry of Pensions in their endeavour to cure or alleviate the condition of those officers and men who unfortunately suffered from mental and nervous diseases due to their war service. Approximately 75,000 officers and men had been pensioned for nervous diseases alone and had been entitled to receive free medical treatment from the Ministry. Most efficacious forms of treatment had been provided on a most adequate scale with gratifying results. The Ministry had instituted courses of training for medical men in one of their neurological hospitals, and hospitals and clinics had been established staffed with neurological specialists sufficient to meet the very great demand for accommodation. The Ministry had now 14 neurological hospitals, besides a large number of clinics for out-patient treatment. Eighteen months ago it was estimated that of the patients treated in several of the

neurological hospitals belonging to the Ministry between 75 and 80 per cent. had obtained employment and no longer required treatment. In one neurological hospital where the more serious cases were accommodated 134 patients were treated during 1922, and of these only 9 had to be certified as insane, whilst 68 were discharged recovered and 12 were transferred to other institutions, some of them for industrial training. An important part of the continuous treatment provided in the Ministry's neurological hospitals consisted of occupational training.

HOUSE OF COMMONS.

TUESDAY, MARCH 27TH.

Veneral Disease.

Mr. BURGESS asked the Minister of Health the number of men and women, respectively, who were treated for venereal disease in hospitals and other places during 1918, 1919, 1920, 1921, and 1922.—Mr. NEVILLE CHAMBERLAIN replied: The following table shows the number of persons dealt with at the treatment centres for venereal disease in England and Wales during the years in question. These numbers include persons who applied for treatment but were found not to be suffering from venereal disease. Separate figures for males and females are not available for 1918 and 1919.

Year.	Males.	Females.	Total.
1918	—	—	58,000
1919	—	—	128,692
1920	103,567	40,367	143,934
1921	114,692	48,808	163,500
1922	114,632	47,684	162,316

Pension Appeals.

Mr. GRUNDY asked the Minister of Pensions whether he was aware that many men who were successful in their appeal to the pensions appeals tribunal did not receive a further award of pension, and that this was due to the man being re-examined by a board on which a deputy commissioner of medical services sat who was a member of the board that previously examined the man and rejected his claim to be suffering from a disability due to war service; and whether, in view of the grave dissatisfaction that existed among ex-Service men that although successful in appeals against the Ministry decisions they did not receive a pension, he would make arrangements for a travelling medical board to work in conjunction with the pensions appeals tribunal, so that they might assess the claimant's degree of disability independent of any local feeling or prejudice that might exist.—Captain CRAIG replied: I assume that the hon. Member's question relates to decisions of the pensions appeal tribunals "setting aside" final awards. As I have before explained in this House, such a decision merely implies that, in the opinion of the tribunal, the disablement of the man has not arrived at a point at which it is unlikely within a reasonable time to get either worse or better, and that therefore the time has not arrived to make the award final. It does not mean that the tribunal consider the assessment to be wrong at the time. It means that the tribunal think it may become wrong later in case of a change in the man's condition, and that they therefore wish to defer a final decision. With regard to the alleged dissatisfaction amongst ex-Service men that although successful in appeals they do not receive compensation from the Ministry, I would point out that it must frequently happen that a board examining a man shortly after the tribunal have set aside his final award find that the man's degree of disablement is precisely the same as when the final award was made and that consequently there is at the time no ground for any further award.

Mr. FREDERICK ROBERTS asked the Minister of Pensions on what basis a final award was given to a man suffering from a disease due to war service; and was he aware that medical opinion agreed that it was not possible at any time to say that a man's condition, as the result of disease, had reached a final and stationary condition.—Major TRYON replied: The principles on which final awards are made are laid down in the War Pensions (Final Awards) Regulations, 1922, and the War Pensions (Final Awards) Amendment Regulations, 1923, but I would refer the hon. Member more particularly to regulation 8. As regards the second part of the question, the hon. Member will see from these regulations that a final award is made in a disease case when, taking a reasonably near view, it has reached a condition in which further material fluctuation is unlikely.

Mr. BARKER asked the Minister of Pensions the number of cases of officers heard before the appeal tribunals during the two years ending Dec. 31st, 1922; the number of cases of non-commissioned officers and the number of cases of privates heard before the appeal tribunals during the same

period; and the number of successful appeals in each rank per cent.—Major TRYON replied: Approximately 1400 appeals by officers, and 70,000 appeals by other ranks were decided by the entitlement tribunal during the period mentioned. The percentage of these appeals allowed were 48 and 26 respectively. The form in which the records of my department are kept do not enable me to give separate figures for non-commissioned officers and privates.

WEDNESDAY, MARCH 28TH.

Death-rate from Cancer.

Major MOLLOY asked the Minister of Health what was the death-rate from cancer in Great Britain at the present time; what was the death-rate from this disease during each of the previous four decades; what proportion of deaths from all causes, other than accident or violence, were due to this scourge; and what financial provision was made by His Majesty's Government towards assisting those engaged in fighting this plague by their endeavours to ascertain its causes and the best means of combating its ravages.—Mr. NEVILLE CHAMBERLAIN replied: The standardised death-rates from cancer in England and Wales in the four decades, 1881-1890, 1891-1900, 1901-1910, and 1911-20, and in the year 1921 were 610, 767, 867, 966, and 1007 per million of the population respectively. In England and Wales the cancer deaths during the above decades represented 3.2, 4.3, 6.1, and 8.0 per cent. of the total deaths from all causes, other than those due to accident and violence. The promotion of cancer research is among the purposes for which an annual subsidy is made by Parliament to the Medical Research Council, and the Council from time to time make grants in aid of investigations which may bear on the incidence, causation, and treatment of cancer. The Council also have in their charge a quantity of radium salt belonging to His Majesty's Government, and with this have organised an investigation into the treatment of cancer by means of radium in ten different hospitals in this country. My hon. friend is, no doubt, aware that an extensive research into the causes of the disease has for some time past been undertaken by the Imperial Cancer Research Fund.

Blind School-children.

Mr. SHORT asked the Minister of Health the number of children of school age who were blind or partially blind.—Mr. NEVILLE CHAMBERLAIN replied: The latest estimates which I have received from local education authorities in England and Wales of the number of children of school age in their areas who are blind or partially blind relate to the year 1920 and give a total of 5800.

The Spahlinger Treatment.

Mr. CECIL WILSON asked the Minister of Health whether his attention had been called to the Spahlinger treatment for tuberculosis; whether his department had made or could make any report in regard to it; and whether the British Red Cross Society had allocated any and, if so, what sum for this treatment.—Mr. NEVILLE CHAMBERLAIN replied: As regards the first two parts of the question, I would refer the hon. Member to the previous answers given on the subject. As regards the last part, I understand that certain negotiations have been taking place between the British Red Cross Society and M. Spahlinger, but so far as I am aware no definite arrangements have yet been concluded.

Pension Appeals.

Mr. PIELOU asked the Minister of Pensions the number of appeals to the assessment appeals tribunal up to Dec. 31st, 1922, showing the number allowed by the tribunal and the number disallowed by the tribunal.—Captain CRAIG replied: Approximately 13,050 appeals against final awards were decided by the tribunal up to Dec. 31st, 1922. Of these, about 62 per cent. had the final award confirmed unaltered; 19 per cent. had the final award confirmed at a higher assessment; and 19 per cent. were set aside by the tribunal.

Mr. PIELOU also asked the Minister of Pensions the figures showing the number of final awards made up to Dec. 31st, 1922, as follows: Final awards of less than 20 per cent., including nil awards, and final awards of more than 20 per cent.—Captain CRAIG replied: The number of awards which have become final awards up to the date mentioned is approximately as follows: Nil and less than 20 per cent. awards, 153,000; awards of 20 per cent. and over, 40,000.

Mr. STEPHENS asked the Attorney-General, if, in view of the complaints with the decisions of the pensions appeal tribunals, he was prepared to appoint a special committee to inquire into the procedure and method of arriving at decisions of those tribunals, such committee to be comprised of representatives of the various ex-Service men's associations, of the trade-unions, and of the Ministry of Pensions, so that it might commend the confidence of the working class.—Colonel GIBBS replied: No complaints have reached me of the procedure of pensions appeal tribunals. The

procedure is regulated by rules made by the Lord Chancellor under the statute. He will at any time be ready to consider any recommendations that may be made for its improvement. The methods are the same as those adopted by all tribunals in this country which have to arrive at conclusions of fact, and it does not appear to me that any inquiry into those methods is necessary. I do not accept the suggestion that there is any general complaint against the decisions. The fact that an unsuccessful appellant expresses dissatisfaction cannot be accepted as evidence that a decision is unjust and the British Legion have, on more than one occasion, indicated the confidence of themselves and those whom they represent in the tribunals.

Entitlement and Assessment Tribunals.

Mr. FREDERICK JOWETT asked the Attorney-General, respecting the pensions appeal tribunals, if he would give the names and state the qualifications of the 12 entitlement and the 18 assessment tribunals.—The qualifications of entitlement tribunals are set out in the schedule to the War Pensions (Administrative Provisions) Act, 1919: (1) Chairman, a barrister or solicitor of not less than seven years' standing; (2) a disabled officer who has retired or been demobilised from His Majesty's Forces during the present war whilst suffering impairment, or a disabled man who has similarly been discharged or demobilised; and (3) a duly qualified medical practitioner.

The War Pensions Act, 1921, Section 4, Subsection 3, proviso B, provides that for assessment tribunals "the constitution of the tribunals shall be modified by the substitution for the legal representative of a second medical practitioner having such qualifications as may be prescribed by regulations made under the schedule to the Act of 1919," and the rules made under the schedule provide "that the medical member to be substituted for the legal representative under Subsection 3, proviso B of the War Pensions Act, 1921, shall be a duly qualified medical practitioner of not less than ten years' standing."

Number and Cost of Pensions in 1922.

Mr. TREVELYAN THOMSON asked the Minister of Pensions the total amount of pensions paid during 1922 to, and the number of parents or relatives, other than widows, in receipt of war pensions on account of loss of friends or relatives during the European war.—Major TRYON replied: The average number of pensions in payment by my department during the year 1922 to dependents, other than widows, but including motherless children, was approximately 385,000. The total expenditure on these awards during the same year was about £9,300,000.

Pensions for Insanity.

Sir EDWIN STOCKTON asked the Minister of Pensions how many cases he had had within each of the last six months in which the medical advisers of the Ministry had declined to accept the mental derangement of the applicants as due in any way to or aggravated by war service; whether he was aware that there was growing dissatisfaction with the official treatment of these cases; and whether he would modify the system of treating these cases so as to satisfy this feeling.—Major TRYON replied: The number of rejected applications for pension for insanity were: During September, 34; October, 16; November, 57; December 34; January, 52; and February, 58. I am satisfied that this type of case receives most sympathetic consideration, and I would point out that, in cases of dissatisfaction with the Ministry's decision, there is a statutory right of appeal to an independent tribunal, by whose decision the Ministry is bound.

THURSDAY, MARCH 29TH.

Dangerous Drugs Regulations.

Major MOLLOY asked the Secretary for the Home Department if the amendment to the regulation, dated Oct. 2nd, 1922, amending Regulation 5 of the principal regulation of the Dangerous Drugs Regulations, dated May 20th, 1921, would be annulled.—Mr. BRIDGEMAN replied: Yes, Sir. I propose to make a regulation revoking No. 1 of the amending regulations made on Oct. 2nd, 1922, under Section 7 of the Act.

Permanent Disablement Pensions.

Mr. SHORT asked the Minister of Pensions the number of permanent disablement pensions granted up to date to officers and men.—Major TRYON replied: The number of final awards and pensions now in payment is about 110,000.

Alternative Pensions.

Mr. SHORT asked the Minister of Pensions the total number of alternative pensions now being paid to disabled officers, disabled men, and widows, respectively.—Major TRYON replied: The approximate numbers of awards of alternative pensions at present in payment are: 300 to officers and nurses; 1800 to other ranks; 2200 to widows of officers; and 30,900 to widows of other ranks.

Technical Services of Fighting Forces.

Lieut.-Colonel FREMANTLE asked the Under-Secretary of State for War if the Government had considered the report of the committee dealing with the coördination of the technical services of the Navy, Army, and Air Force; if so, what action, if any, was proposed as a result; and what opportunity would be given for such proposals to be considered and discussed by the House.—Mr. GWYNNE (Financial Secretary to the War Office) replied: The answer to the first part of the question is in the affirmative, and steps are being taken, particularly by the establishment of inter-departmental technical committees, to carry out the necessary detailed measures of coördination. With regard to the last part of the question, it is not proposed to publish the report of the committee.

Schools for Mental and Physical Defectives.

Mr. SHORT asked the President of the Board of Education the number of special schools provided for children of school age who were mentally and physically defective, and the number of children attending such schools.—Mr. EDWARD WOOD replied: The number of special schools for mentally defective children is 199, and on March 31st, 1922, there were 15,975 children on the registers of those schools. The corresponding figures for physically defective children are 203 and 14,419.

Medical News.

SOCIETY OF APOTHECARIES OF LONDON.—At examinations held recently the following candidates passed in the subjects indicated:—

Surgery.—K. C. Chock, Creighton University, U.S.A.; M. K. El Khadem, Liverpool; M. A. Lawson, Royal Free Hosp.; and M. Mc. W. Lopez, Bristol and Univ. Coll. *Medicine*.—M. A. Lawson, Royal Free Hosp. *Forensic Medicine*.—G. K. Butterworth, St. Mary's Hosp.; M. Hawke, Guy's Hosp.; C. M. John, Madras and Royal Free Hosp.; and M. A. Lawson, Royal Free Hosp. *Midwifery*.—G. K. Butterworth, St. Mary's Hosp.; K. C. Chock, Creighton University, U.S.A.; M. Hawke, Guy's Hosp.; H. Hirst, Manchester; M. A. Lawson, Royal Free Hosp.; and H. M. White, Leeds.

The Diploma of the Society was granted to the following candidates entitling them to practise medicine, surgery, and midwifery: G. K. Butterworth, K. C. Chock, H. Hirst, M. A. Lawson, and H. M. White.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH.—

At a recent diet, out of 54 candidates entered the following passed the Final Dental Examination and were granted the diploma L.D.S. R.C.S. Edin:—

Gilbert A. Loots, William Mason, Robert G. Doig, Arthur H. Wynne, Robert P. Anderson, Henry A. Andrew, Frederic L. Jones, Peter B. Laurensen, Henry D. McDonald, Stanley Still, Henry S. Stowe, Bernard Abbott, Elsbury M. Forehand, Claudius A. G. Roose, John MacArthur, John M. Thomson, John H. Millar, Jean M. Keisler, Arthur W. Wallace, Harold Robinson, Alexander Essiman, William A. Sutherland, John Harkness, David S. Middleton, James A. Whitelaw, Stuart L. Melver, and Harold H. Balfe.

The following candidates passed in the subjects of Pathology, Medicine, and Surgery:—

Robert Bell, William Guild, Archibald T. Donaldson, John B. Forgan, Ian D. J. Smith, Henry F. Skinner, Hector G. Robb, Francis Mackenzie, Robert C. Cook, Alexander W. Seaton, and James Barron Cowie.

The following passed in the subjects of Medicine and Surgery: Thomas E. Mathias, Charles J. Coventry, and David R. Paterson.

UNIVERSITY OF ABERDEEN: SPRING GRADUATION.

The spring graduation took place on March 28th. A feature of the graduation was the large number of ex-Service men capped. Practically all the male graduates in medicine had seen active service. In his address at the close of the ceremony, the Vice-Chancellor, Principal Sir George Adam Smith, who presided in the absence of the Chancellor, the Duke of Richmond and Gordon, alluded to these facts as making it a memorable graduation. An interesting coincidence was the capping of father and daughter in the Faculty of Medicine—namely, Ernest St. Clair Henriques, M.B., C.M. (Old Regulations), who graduated M.D., and Stella Grace Alice Henriques. Among the degrees conferred were the following:—

DEGREE OF DOCTOR OF LAWS (LL.D.).

Dr. William Mackie, Fellow and past Vice-President, Edinburgh Geological Society; and Sir George Henry Makins, consulting surgeon, St. Thomas's Hospital and Evelina Hospital for Sick Children, London.

DEGREE OF DOCTOR OF MEDICINE.

George R. McRobert (commendation for thesis), Henry Duguid, Ernest St. Clair Henriques, and Matthew Logg.

DEGREE OF M.B. AND CH.B.

With Second-Class Honours.—*James D. Murray, Louisa B. Park, *Jane E. Riddoch, and *Richard R. Trail.

Ordinary Degree.—Ronald Anderson, Jeannie G. Angus, Joseph W. Balnaves, Jacob M. Bayer, Alexander S. Benzie, Abraham B. Berkowitz, Muriel E. Bruce, Forbes S. Catto, Alex. I. Cheyne, *John H. Clifford, Clement A. Cowie, Alexander Craig, Helena M. Davidson, Robert H. G. H. Denham, Israel M. Dove, James Duncan, Herbert A. Eccles, Jean L. Farquhar, Alexander Findlay, *Robert P. Gammie, Thomas P. Gill, *Wallace J. Gill, Richard O. Girdwood, Ian L. V. L. Gordon, Stella G. A. Henriques, Edward James, William T. B. Joss, Christina F. Kerr, Christina R. Laing, Beatrix B. Law, William M. Ledingham, Solomon Lewin, James P. Lillie, William E. McCulloch, Ian W. MacGregor, David H. MacKenzie, *Joseph M. McKenzie, Christopher D. Macrae, George McD. Mitchell, William R. Mitchell, Gordon G. J. Mutch, *Walter J. Ogilvie, Marjorie I. Outram, Wilson H. G. Park, Alexander W. Paterson, Margaret E. Rankin, Ian M. Rhind, *Johannes de Ridder, Jeanie H. Ritchie, Lawrence D. Robertson, Harry P. Samson, Frederick R. Sleigh, Elizabeth L. L. Smith, Hugh G. T. Smith, Cecil V. Spark, Constance S. Steele, Mary H. Stephen, William H. Stephen, James Strachan, Hilda J. Third (née Badenoch), Dirk Tom, Hugh Trail, Hugh G. Watson, and William W. Wilson.

* Completed Final Medical Professional Examination with distinction.

DIPLOMA IN PUBLIC HEALTH.

Adam Hutton, Victor E. Milne, John I. Moir, and William L. Stephen.

University Prizes.—Fife Jamieson Memorial Gold Medal in Anatomy: Wilfrid Marshall. Keith Gold Medal for Systematic and Clinical Surgery: Alexander Lyall. Shepherd Memorial Gold Medal for "The Principles and Practice of Surgery": Richard R. Trail. Dr. James Anderson Gold Medal and Prize in Clinical Medicine: Alexander Lyall. Matthews Duncan Gold Medal in Obstetrics: William Gunn. The Alexander Ogston Prize in Surgery: Walter J. Ogilvie.

UNIVERSITY OF LIVERPOOL.—At examinations held recently the following candidates were successful:—

FINAL EXAMINATION FOR DEGREES OF M.B. AND CH.B.

Part I., Pathology.—C. P. Allen, A. Ashworth, P. D. Barling, T. Bellis, E. C. Benn, T. A. Clarke, H. A. Cole, R. Cotter, E. A. R. Evans, M. Fisher, F. F. Fuller, G. A. Garrett, M. Godwin, W. J. Griffiths, L. F. Henry, F. C. S. Hinsbeeck, S. Howard, Enid M. Hughes, Bertha H. Irvine, R. C. Jones, E. Miles, D. H. Mills, J. R. Oddy, A. Oserovitz, E. R. S. Owen, P. Strelitz, A. C. Terry-Thompson, J. J. du Toit, and B. J. van de S. de Villiers.

Part II., Forensic Medicine, Toxicology, Public Health.—J. M. Brodrick, G. E. Church, R. Y. Dawbarn, J. C. Drummond, Clara M. V. Gleave, D. C. G. Hanlon, W. F. Jones, T. S. King, W. J. Laird, C. Sharp, and N. Weinberg.

SECOND EXAMINATION FOR DEGREES OF M.B. AND CH.B.

Part A., Anatomy and Physiology.—H. E. Barrow, A. S. A. Brown, R. F. Corlett, D. E. Davies, J. Hatton, H. O. A. Meyer, E. P. Moloney, W. J. Pierce, J. E. Walker, and W. L. Webb.

Part B., Materia Medica, Pharmacy, Pharmacology.—M. M. F. Arthur, D. Cohen, O. Dawood, W. Emden, A. J. Goss, J. Graham, Catherine E. I. Greenshields, F. P. Irvine, Elvey I. Johnstone, D. Katz, Rebecca Katz, B. Kay, B. D. Knoblauch, E. A. Martinez, P. Strelitz, and R. S. Turner.

DIPLOMA IN PUBLIC HEALTH.

Doris M. Cassidy, E. R. Peirce, and G. H. Potter.

DIPLOMA IN TROPICAL MEDICINE.

D. Basu, J. C. Cruickshank (recommended for the Alan H. Milne Medal), Winifred I. Doherty, J. Elsohn, R. N. Raja, and C. F. White.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—An extraordinary Comitia was held on March 26th, the President, Sir Humphry Rolleston, being in the chair.—The annual address was delivered by the President. He compared the numbers on the College list at the present time with those of 100 years ago. There were now 368 Fellows instead of 88, and 600 Members instead of 216. The licentiates now number 14,448, and there was one extra licentiate. He then read obituary notices of the ten Fellows who have died during the past year—viz., Dr. Robert Shingleton Smith, Sir Henry Davy, Dr. W. H. R. Rivers, Sir Edward Malins, Dr. Arthur Ransome, Dr. Cornelius Benjamin Fox, Sir James Galloway, Sir Norman Moore, Dr. John James Pringle, and Dr. Norman Dalton.—On the motion of Sir William Church the thanks of the College were given to the President for his address.—Sir Humphry Rolleston then vacated the chair and the College proceeded to the election of president. Sir Humphry Rolleston was re-elected, obtaining 61 votes out of 65.—Communications were received from the clerk to the Privy Council informing the College that the Seventh International Congress on Thalasso-Therapeutics will be held at Venice on April 9th–12th next; and from the Secretary of the Ministry of Health informing the College that the celebrations (in France) of the centenary of the birth of Pasteur will include a conference on leprosy, to be held at Strasbourg on July 28th–31st next.—The College authorised the presentation of an illuminated address to H.R.H. the Prince of Wales, President of St. Bartholomew's Hospital, at the celebration of the 800th anniversary of the foundation of the hospital.—The President then dissolved the Comitia.

Messrs. William Heinemann (Medical Books), Ltd., announce that commencing with Volume IV. (May, 1923), they have undertaken the publication of the *Journal of Neurology and Psychopathology*.

Mr. G. R. Anderson, M.B.E., F.R.C.S. Eng., senior honorary medical officer to the Southport Infirmary, has been placed on the Commission of Peace for the county borough of Southport.

LETHARGIC ENCEPHALITIS IN MANCHESTER.—During the past fortnight four cases of "sleepy sickness," all of which proved fatal, were reported in Manchester, the victims being seamen who had arrived at the Ship Canal docks from foreign ports.

HUNTERIAN SOCIETY.—The last dinner meeting will be held at Simpson's Restaurant, Cheapside, on Monday, April 9th, at 7.30 P.M. After dinner a discussion on Toxæmia of Pregnancy will be introduced by Mr. L. Carnac Rivett, in which Mr. Victor Bonney and Mr. A. Bourne are expected to participate.

RONTGEN SOCIETY.—A general meeting will be held on Tuesday, April 10th, at 8.15 P.M., in the Institution of Electrical Engineers, Savoy-place, Victoria Embankment, London, W.C.2, when Mr. Mortimer A. Codd, F.Ph.S., will read a paper on a New Method of Operating Induction Coils, followed by a demonstration of the apparatus.

THE LATE DR. G. C. PURVIS.—George Carrington Purvis, M.D., B.Sc. Edin., formerly medical officer of health for Grahamstown, died recently in that city. Dr. Purvis was Thomson Scholar and Falconer Fellow at the University of Edinburgh and had devoted much time and attention to the study of tropical diseases and to the ætiology of cancer. His son, who also studied at Edinburgh University, is now the government veterinary surgeon at Eldoret, Kenya.

QUEEN SQUARE HOSPITAL.—Sir Frederick Macmillan presided last week at the annual meeting of governors at the National Hospital for the Paralysed and Epileptic, Queen-square. The report of the board of management showed that, mainly owing to the fall in the cost of supplies and a substantial grant from the Hospital Combined Appeal, the hospital had more than paid its way during 1922. Funds are urgently required for a new out-patient theatre, an enlargement of the electrical department, and some essential improvements to the convalescent home at East Finchley.

SMALL-POX AT NELSON AND CLOWNE.—In the last week in March 7 new cases were reported at Nelson, 5 being members of one household, making a total to date of 37 cases. The health committee have decided to close day schools and Sunday schools for a month, and children are to be prohibited from attending kinemas. Many proposed public entertainments have been postponed. A large extension to the Infectious Diseases Hospital at Catlow has been erected.—The small-pox outbreak in the Clowne district of Derbyshire, which gave signs of abatement as a result of the large number of vaccinations, again shows activity, as last week five more cases were reported, making a total of 85 cases since last summer.

THE DIPLOMA OF PSYCHOLOGICAL MEDICINE.

The details of the first part of the sixth course of lectures and demonstrations for the Diploma in Psychological Medicine have now been announced. The course will commence at the Maudsley Hospital, Denmark Hill, S.E., on May 1st, with a series of eight lectures on the Anatomy of the Nervous System, by Sir Frederick Mott, lately pathologist to the London County Mental Hospitals, who remains to assist the Maudsley Hospital in an advisory capacity. Sir Frederick Mott's lectures will be on Tuesdays at 2.30 P.M. On Thursdays, at 2.30 P.M., commencing on May 3rd, eight lectures will be delivered by Dr. Henry Devine on Psychology; and at the same hour on Fridays, and commencing on May 4th, eight lectures will be delivered on the Physiology of the Nervous System. Practical instruction and demonstrations will accompany each course, and the whole fee for Part I. separately is 10 guineas, the fee for any one series of lectures being 4 guineas. The second part of the course will commence in October, will deal with Symptomatology, Pathology, and Treatment of Mental Disease, and a more detailed syllabus will be published in due course. A composition fee can be paid of 15 guineas for the two parts. All inquiries should be addressed to the Director of the Pathological Laboratory at the Maudsley Hospital, and application forms, when obtained, should be returned with the appropriate remittance to the cashier, London County Council, County Hall, Westminster Bridge, S.E.1. Medical men intending to take the course, who are introduced by the Fellowship of Medicine, can pay their fees and receive their tickets from the Fellowship on application to 1, Wimpole-street, W.

ROYAL NAVY MEDICAL CLUB.—The annual dinner will take place at the Trocadero Restaurant (Balmoral Room), Piccadilly Circus, London, W. 1, on Thursday, April 19th, at 7.30 for 8 P.M. Members who wish to be present are asked to inform the hon. secretary, Royal Navy Medical Club, 68, Victoria-street, S.W. 1, not later than seven clear days before that date.

ROYAL COLLEGE OF SURGEONS OF ENGLAND:
ELECTION TO THE COUNCIL.—Five vacancies now occur on the Council of the College, Sir William Thorburn having died since the issue of the last notice; they will be filled by election on Thursday, July 5th, 1923. The following are the names of the candidates with the date affixed of admission to the Fellowship: Sir H. F. Waterhouse (1890), standing for re-election; Mr. James Berry (1885); Mr. J. H. Fisher (1893); Mr. H. J. Paterson, C.B.E. (1897); Mr. Sampson Handley (1897); Mr. T. P. Legg, C.M.G. (1897); Mr. Victor Bonney (1899); Mr. D. Armour, C.M.G. (1900); Mr. Percy Sargent, C.M.G., D.S.O. (1900); Mr. G. E. Gask, C.M.G., D.S.O. (1901); and Mr. G. Grey Turner (1903).

ABERDEEN DISPENSARY AND VACCINE INSTITUTION.—The annual meeting was held in the Town House, Aberdeen, on March 29th, Lord Provost Meff presiding. The annual report showed that the total number of cases treated in all departments during the year was 5544, compared with 3646 in the previous year. The number of patients treated at their own homes during the year by the general staff of the dispensary was 2344, compared with 1059 in the previous year, while the number of visits paid was 6644, compared with 2461 in 1921. The number of vaccinations performed during the year was 49, an increase of 13. The number of dental operations performed was 176, an increase of 42. The special ear, nose, and throat cases during the year numbered 366. The number of operations carried out during the same period was 103. During the year 76 persons applied for treatment at the ophthalmic department. In the department for the diseases of women 190 patients were treated. 21,735 prescriptions were dispensed. During the year Dr. John Johnston was appointed anaesthetist and Dr. Alex. Brown a district medical officer; Dr. Douglas R. Dugan was also appointed a district medical officer.

OXFORD MEMORIAL TO THE LATE SIR WILLIAM OSLER.—A final meeting of the subscribers to the Memorial Fund was held on March 15th at the University Museum, Oxford, Sir Herbert Warren, President of Magdalen College, presiding. The following proposals were submitted on behalf of the Committee.

1. The purchase of a bronze plaque of Sir William Osler, measuring 32 by 22 inches, a copy of that, by Vernon of Paris, made for the Medical Faculty of Maryland, this plaque to be hung in the University Museum.

2. The establishment of a fund for the foundation of an Osler Memorial Medal in bronze, to be awarded every five years to a graduate of the University of Oxford who has made some distinguished contribution to medical science, learning, or practice. This medal might be a reduced replica of the portrait plaque.

3. The remainder of the sum, together with any sums hereinafter added, to be called the "Osler Travelling Fund" for the propagation or acquisition of medical knowledge or for medical research, this fund to be invested and the interest utilised to assist teachers of the medical faculty to travel for the above purposes. It is estimated that the capital sum remaining for this purpose will be about £1700.

Sir Archibald Garrod stated that these proposals had the entire approval of Lady Osler, as well as of other friends from whom letters had been received; they were supported by Surg.-Major-General Sir Frederick Bradshaw, and adopted nem. con. The Executive Committee, which consists of Sir Herbert Warren (chairman), Sir Archibald Garrod, Sir Charles Sherrington, Prof. Arthur Thomson, Mr. A. P. Dodds-Parker (hon. treasurer), and Prof. J. A. Gunn (hon. secretary), was empowered to take steps to carry the proposals into effect and in particular to negotiate any arrangements with the University which may be found desirable. Any further subscriptions should be sent without delay to Mr. Dodds-Parker, 2, Holywell, Oxford.

ROYAL SUSSEX COUNTY HOSPITAL: REOPENING THE CLOSED WARDS.—A beginning has been made in re-opening the wards of the County Hospital at Brighton, which for financial reasons were closed in October last. On March 27th 20 beds in the detached Jubilee Block were opened for the use of patients who cannot afford nursing home fees and yet are hardly suitable cases for the general wards of the hospital. Patients will be called upon to pay not less than £3 and not more than £4 per week. This sum will not cover the cost, but the John Howard Trustees have agreed to make up any deficiency there may be, as an experiment for two years. The reopening ceremony was performed by the Public Trustee, Mr. O. R. A. Simpkin, who said that the sum of £10,000 left by the late Sir John Howard would not,

on present values, build a nursing or surgical home. The trustees therefore had approached the governors of the County Hospital for co-operation in carrying out the testator's wishes, and it was agreed that the trustees should redecorate and re-equip two wards of the hospital to be named the "John Howard" wards. The chairman of the governors, Mr. R. Ball Dodson, pointed out that these wards for people of moderate means were not in any way to be a rival to existing institutions. Those who occupied them must be able to convince the authorities that they were not in a position to bear the expense of a nursing home and a first-class surgeon.—Four days later, on March 31st, 30 beds in the main building were reopened in accordance with the arrangement with the Ministry of Health, the hospital thus qualifying for the grant of £3950 from the Voluntary Hospitals Commission. Thus 50 beds still remain closed, but it is hoped to reopen these by September.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Monday, April 9th.

WAR: at 4.30 P.M.

Annual General Meeting:

Election of Officers and Council for 1923-24.

Paper:

Squadron-Leader T. F. Rippon, R.A.F.: The Effects of Tropical Climate on Mental and Physical Efficiency.

Tuesday, April 10th.

THERAPEUTICS AND PHARMACOLOGY: at 4.30 P.M.

Annual General Meeting:

Election of Officers and Council for 1923-24.

Paper:

Prof. F. Hobday: The Idiosyncrasy of Animals to Strychnine, Morphine, and Mercury.

Wednesday, April 11th.

SURGERY: SUB-SECTION OF PROCTOLOGY: at 5.30 P.M.

Paper:

Sir Charters Symonds: Nephrostomy for the Relief of Inoperable Recto-vesical Fistula.

Cases

Will be shown by Sir Charles Gordon-Watson, Mr. Lockhart-Mummery, Mr. Hamilton Drummond, Mr. Herbert Brown, and Mr. Donald Armour.

Thursday, April 12th.

NEUROLOGY: at 8.30 P.M.

Paper:

Sir Frederick Mott: Myasthenia Gravis.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, London, W.C.

FRIDAY, April 13th.—5 P.M., Museum Demonstrations, Sir Arthur Keith: Madder-stained Specimens illustrating the Process of Bone Growth.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith-road, W.

MONDAY, April 9th.—10 A.M., Mr. MacDonald: Genito-Urinary Dept. 2 P.M., Mr. Addison: Surgical Wards. 3 P.M., Mr. Simson: Diseases of Women.

TUESDAY.—10 A.M., Mr. Steadman: Dental Dept. 12 noon, Dr. Burrell: Chest Cases. 2.30 P.M., Dr. Pritchard: Medical Wards.

WEDNESDAY.—10 A.M., Dr. Saunders: Medical Diseases of Children. 2.30 P.M., Mr. Donald Armour: Surgical Wards. 2 P.M., Mr. Gibb: Eye Dept.

THURSDAY.—2 P.M., Mr. Bishop Harman: Eye Dept. 3 P.M., Dr. Scott Pinchin: Medical Out-patients. 3 P.M., Mr. Simmonds: Surgical Out-patients.

FRIDAY.—10 A.M., Dr. Drummond Robinson: Gynaecological Operations. 2 P.M., Mr. Banks Davis: Diseases of Throat, Nose, and Ear. 3 P.M., Mr. Simmonds: Surgical Out-patients.

SATURDAY.—9 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Saunders: Medical Diseases of Children. 11 A.M., Mr. Maingot: Surgical Pathology.

Daily, 10 A.M. to 6 P.M., Saturdays, 10 A.M. to 1 P.M., In-patients and Out-patients, Operations, Special Departments.

QUEEN CHARLOTTE'S LYING-IN HOSPITAL, Marylebone-road, N.W.

THURSDAY, April 12th.—5 P.M., Mr. L. C. Rivett: Toxæmia of Pregnancy.

UNIVERSITY OF BRISTOL POST-GRADUATE DEMONSTRATIONS (in the Medical Theatre).

THURSDAY, April 12th.—3.30 P.M., Mr. A. J. Wright: Nasal Catarrh.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE LECTURES.

TUESDAY, April 10th.—4.15 P.M., Dr. D. E. Core: Some Points in the Differential Diagnosis of Pain.

FRIDAY.—4.15 P.M., Mr. W. R. Douglas and Mr. J. M. W. Morison: The Diagnosis and Surgical Treatment of Lesions of the Large Intestine.

ANCOATS HOSPITAL.

THURSDAY, April 12th.—4.30 P.M., Dr. H. Holmes: Demonstration of Pathological Specimens with Case Histories.

Appointments.

GARDNER, L. P. M., M.B., Ch.B. Edin., has been appointed Certifying Surgeon under the Factory and Workshop Acts for Leith.

GOWERS, DOROTHY W., Assistant Medical Officer for East Ham. SINCLAIR, NEIL F., F.R.C.S. Eng., Surgeon to Out-patients at the Evelina Hospital for Children.

Vacancies.

For further information refer to the advertisement columns.

- All Saints Hospital for Genito-Urinary Diseases, Vauxhall Bridge-road, S.W.—Res. H.S. £200.
 Bath, Winsley Sanatorium.—Asst. Res. M.O. £250.

 York, North Riding Mental Hospital, Clifton.—Deputy Supt. £500.
 The Chief Inspector of Factories, Home Office, Whitehall, London, S.W., announces a vacant appointment at Stillington (Durham).

Births, Marriages, and Deaths.

BIRTHS.

- DEAN.—On March 26th, at Spilsby, Lincolnshire, the wife of Dr. L. T. Dean, of a daughter.
 EDWARDS.—On March 23rd, at Felixstowe, the wife of H. Vernon Edwards, M.B., B.Ch., of a son.
 MACKENZIE.—On March 28th, at Camden-terrace, Manningham-lane, Bradford, the wife of Colin Mackenzie, O.B.E., F.R.C.S., of a son.

DEATHS.

- BURY.—On April 3rd, at Cloverley, Chinley, Hannah Louisa, beloved wife of Judson S. Bury, M.D., F.R.C.P., in her seventieth year.
 CREAN.—On March 25th, at Queen-street, Mayfair, Major T. J. Crean, V.C., D.S.O.
 HARPER.—On March 30th, in a nursing home, Charles John Harper, M.R.C.S., L.R.C.P., of Hendon-avenue, Finchley in his 67th year.
 MILLIGAN.—On March 27th, 1923, at Cliftonville, Lytham, William Milligan, M.D., M.Ch., M.A.O., aged 64 years.
 SAUNDERS.—On March 23rd, at College-road, Eastbourne, Henry Saunders, M.A., M.R.C.S.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

RESEARCH IN THE CALCUTTA SCHOOL OF TROPICAL MEDICINE.¹

BY ROBERT KNOWLES, M.R.C.S. ENG.,

MAJOR, I.M.S.; PROFESSOR OF PROTOZOOLOGY IN THE CALCUTTA SCHOOL OF TROPICAL MEDICINE.

[AFTER referring to the difficulties encountered in the inception of the research scheme and the sum of Rs.1,80,000 he had collected to supplement the Rs.9,23,836 obtained by public subscription by Sir Leonard Rogers before he left India, totalling about £100,000 at the then rate of exchange, Major Knowles described the opening of work by four whole-time research workers as a result of action of the Endowment Fund Committee in the autumn of 1920, "in anticipation of sanction" by Government, and the completion of the scheme with its own hospital of 116 beds at a total cost of Rs.17,96,711 early in the following year.] He continued:—

The scheme now includes (1) the School of Tropical Medicine for post-graduate teaching and research; (2) the Institute of Hygiene with the Bengal public health laboratory; (3) six special research laboratories with whole-time workers and assistants, financed by the Indian Tea, Jute, and Mining Associations, the Indian Research Fund Association, and private benefactors; and (4) the Carmichael Hospital for Tropical Diseases, with its own out-patient department, to which cases of the special diseases under investigation in the research laboratories are admitted, while 600 more beds in the adjacent Medical College Hospital are also available for research purposes. Under Lieut.-Colonel J. W. D. Megaw, I.M.S., Director of the School and Professor of Tropical Medicine, team-work is here seen at its best, the patient being investigated as a matter of routine by the physician or surgeon, his stools examined for helminths, protozoa, and bacteria by the respective professors of those three subjects, a complete blood examination, including blood cultures and Wassermann reactions, is made; any skin affection is studied in the skin clinic; while a special laboratory and out-patient department are soon to be housed in a new institute opposite the school for leprosy, for which an additional Rs.2,50,000 is now available. Yet another laboratory deals with kala-azar cases under Dr. L. E. Napier, there thus being no less than six special research workers and laboratories devoting their whole time to the investigation of kala-azar, leprosy, ankylostomiasis, dysentery, diabetes, and filariasis and elephantiasis, in addition to the general professorial staff of the school and laboratories, the total staff now totalling 33 research workers all qualified in medicine or science with unlimited clinical material.

Educational Work.

The teaching is purely post-graduate, the first to be fully organised in India, and includes first a six months' cold weather course for the Diploma of Tropical Medicine (limited to 50 selected applicants to allow of individual teaching, over 30 applicants having recently to be refused admission); secondly, a nine months' course in the Institute of Hygiene to prepare men for the university D.P.H.; and thirdly, during three months of the rainy season, for assistant and subassistant surgeons, with an examination for a school certificate. In addition to clinical teaching in the hospital and in special out-patient departments, the daily routine includes a lecture on one subject by the professor, illustrated by lantern slides prepared from plates in the library books and journals, by epidiascope projections, and by cinema films of motile protozoa and other life-cycles, each student being given a copy of a very full and detailed type-stencilled precis of the lecture, so that he can attend to the teaching without having to take notes. In 20 protozoology lectures, for example, 450 lantern slides and 15 cinema films, in addition to the use of the epidiascope, were shown: after a lecture the men proceed to the laboratory to study actual specimens under the microscope illustrating the lecture, and then to the practical classroom to study material of a similar nature. On the following day a different subject is taken, leaving the professor who lectured on the previous day free for research and preparation for his next lecture for the remainder of the week. The course lasts six months, against three in the London and four in the Liverpool School of Tropical Medicine, while the six additional research workers give similar instruction in their special subjects to supplement the systematic courses of the various professors. In the

¹ Abstract of a paper on the research programme of the school read at the annual meeting of the Assam Branch of the British Medical Association, Jan. 7th, 1923.

final examination for the diploma outside examiners assist and the standard in both written and practical work is so high that in the last D.T.M. only 19 out of 29 post-graduates passed, and no one has yet obtained honours.

Research.

Although work is now in progress in no less than 17 different departments of the school, the director has always insisted on co-ordinated and co-operative work, so that three or four departments commonly take part in any one piece of research as will appear from the following very brief outline:—

1. Work on kala-azar is being carried on by the whole-time worker, Dr. Napier, with the help of the entomologist, protozoologist, and pharmacologist. Napier's simple formaldehyde serum test having been placed on a firm basis, examinations of the peripheral blood for the parasites gave 20 per cent. positive, while cultures of the flagellate stage from the peripheral blood was shown to be an almost certain diagnostic procedure, and some 2000 spleen punctures were done without a single ill-result; the disease was found to be more widespread in Bengal than was hitherto recognised. Sodium antimony tartrate continues to give good results, although stibenyl was very disappointing and dangerous, while important systematic work is being done on the difficult problem of the mode of transmission. Major Knowles having recently obtained an acute infection of a monkey experimentally by feeding on a fresh kala-azar spleen; he thinks a sand-fly may prove to be the carrier.

2. Malarial treatment is being investigated by Majors H. W. Acton and R. N. Chopra,² and the value of quinidine in completely eradicating the resistant benign tertian and quartan forms when longer courses of quinine have failed is being confirmed, 10 gr. twice a day of quinidine sulphate in solution for three to six weeks giving 60 per cent. of absolute cures against 20 per cent. by quinine, while the former is also a cheaper drug, so an immense saving will be effected in India; the still cheaper cinchona febrifuge is also very efficient. Spleen punctures in malarial cases have also furnished interesting results.

3. Protozoological and bacterial examinations are made in every dysentery case, a large majority proving to be bacillary in nature, and close investigations of the reactions of the stools by Knowles and Napier revealed that its estimation gives reliable diagnostic indications in the absence of the causative organisms—a most important discovery, which, with the well-established differences in the cellular contents of the stools, promises to enable a rapid diagnosis to be made by simple means apart from well-organised laboratories, which are few and widely scattered in the tropics. Under this head may be mentioned post-mortems on over 500 animals from the Calcutta zoological gardens last year, affording a wealth of intestinal flagellates, &c. Further, Majors Acton and Chopra have obtained poisonous amines from cultures on special media of Flexner as well as Shiga bacilli, and have made experimental tracings illustrating their toxic properties, which promise to throw much light on the nature and treatment of bacillary dysentery, while Flexner bacilli have been found in some sprue-like diarrhoeas.

4. In cholera the two last-mentioned workers have isolated amino-acids and amines and produced choleraic symptoms in animals with them as well as tested their physiological actions with interesting results.

5. As regards dietetic diseases, lathyrism has been shown by Acton to be due to a poisonous amine produced during the germination of *kesari dal* (*Lathyrus sativus*), which has been isolated by the professor of chemistry, Dr. S. Ghosh, and its action tested by Chopra, while symptoms resembling those of lathyrism have been produced in monkeys. In epidemic dropsy another amine has been isolated from the form of stored rice which produces the symptoms, so this disease should also be preventable in future.

6. Ankylostomiasis is being closely investigated by the whole-time research worker in that subject, Dr. J. B. McVail,² who has worked out a simple, rapid, and very effective method of finding the ova, tested the effect of many agents on the larva, shown that the ova will survive septic tank treatment, and confirmed the value of carbon tetrachloride as a very cheap and easily used remedy.

7. Leprosy research has been continued by a whole-time worker, Dr. E. Muir, with valuable results, which will appear in the *Indian Journal of Medical Research*, and include pathological work, mapping out the first discovered lesions in 975 cases, and further confirmation of the value of recent advances in treatment with the extension by two of the number of oils which yield active soluble preparations.

8. Tropical skin diseases are investigated in a special department under Major Acton; photographs and coloured drawings by the whole-time laboratory assistants in charge of that branch are being accumulated, together with cultures and microscopical examinations of the fungi, &c., found in

the numerous cases, which promise in time to place this difficult and very confused subject on a clearer and firmer basis, while important work is also proceeding on tropical ulcer, which is such a serious cause of labour loss on Assam tea-gardens.

9. Indigenous drugs form the special field of investigation by Major Chopra, with the active help of the chemical department, these laboratories being the first adequately equipped for this purpose in India: specimens of the best known indigenous drugs, including berberine and other reputed antimalarial drugs, are being collected and analysed, and their active principles are being investigated pharmacologically and therapeutically. It is hoped in time to ascertain which of the numerous remedies used by the ancient Indian systems of medicines are of value and supply cheaper and more efficient drugs than those now imported at great cost from Europe.

In order to ensure wide publicity to the various practical advances made by the Calcutta school, the publishers of the *Indian Medical Gazette* have generously extended considerably the pages of that long-established monthly journal, so that additional material may be published without curtailing the clinical columns. The remaining lines of research can only be mentioned: they include whole-time laboratory work on filariasis, diabetes, and dysentery; while the Hygiene Institute is doing important work in standardising water and food analyses for India, methods of clearing waters, &c.

This very condensed account of the activities of the Calcutta School of Tropical Medicine and Hygiene will suffice to show that it has already established a leading position among the medical research and post-graduate institutions of the Empire.

THE IRISH DISPENSARY SYSTEM.

THE conditions of work in the Irish dispensary service have long excited uneasiness both among doctors and social workers. Conditions are in such a state of rapid flux in Ireland that drastic change may well be hoped for, and Dr. T. Hennessy has taken the opportunity to make a forcible protest in the Royal Academy of Medicine in Ireland. The subject is dealt with in the current issue of the *Irish Chemist and Druggist*, a new journal edited by a medical man, Dr. James A. Walsh. It is admitted that the dispensary houses are cold, cheerless, and often smoky hovels, where poor people and young babies may have to wait hours in wet clothes for their turn to see the doctor, who has himself to discharge the triple duties of medical adviser, nurse, and dispensing chemist. This system is disliked as much by the doctors as by the chemists, for it is common knowledge that the medical officers are obliged to stay in the service long after they wish to retire on account of the miserable rate of pension offered. The situation has been rendered worse by the amalgamation of the Irish workhouses, which has resulted in abolition of the district hospitals and in a number of urban and rural districts with populations of 20,000 to 30,000 being left without any hospital beds. The county hospitals are not only remote, but generally ill-equipped into the bargain. Nothing short of legislation can deal with so fundamental a disorder.

INSTRUCTION IN SEX MATTERS.

To the Editor of THE LANCET.

SIR.—With reference to the query of "F. C." in THE LANCET of Jan. 20th I would state that an excellent book for the purpose is "Sane Sex Life and Sane Sex Living" by H. W. Long, M.D., Capt. M.R.C., published by Richard G. Badger, Boston. This book is sold only to physicians, or under their order, to comply with our grandmotherly legislation.

I am, Sir, yours faithfully,

A. W. HENZELL.

St. Stephen's College, Annandale on Hudson, N.Y.,
Feb. 26th, 1923.

ST. MARY'S HOSPITALS, MANCHESTER.

To the Editor of THE LANCET.

SIR.—In your review of Dr. I. W. Bride's interesting History of St. Mary's Hospitals, Manchester, you state it is not clear as to what was the ultimate fate of the Quay-street Hospital, Manchester. At the time of the removal of St. Mary's Hospital, I was secretary of Manchester Children's Hospital, Pendlebury, and Gartside-street, Manchester, and as my board were rebuilding the out-patient department, we rented the old St. Mary's Hospital in order to carry on the out-patient work. After we had vacated the premises they were, I believe, demolished.

I am, Sir, yours faithfully,

H. J. EASON.

Harrow-road, London, W., March 31st, 1923.

² THE LANCET, March 3rd, p. 454.

RAT CAMPAIGN IN SALFORD.

THE Superintendent of the Lighting and Cleansing Department of Salford in a report states that under the Rats and Mice Destruction Act of 1919 something like 1500 visits have been made to buildings frequented by rats in the borough. Of 11,576 poisoned baits laid, 4551 were taken, and in addition 3133 rats have been caught by traps, dogs, or ferrets. In 12 months the port sanitary authority treated 140 vessels in port for rat destruction resulting in a total catch of 6812, while more than 3000 were trapped in the dock-sheds and warehouses. Frequent and periodical "drives" of rats in the depôts and corporation tips have diminished the number of rats to a remarkable extent. When information is received as to the presence of rats an investigation at once is made with satisfactory results.

THE CONTINENTAL ANGLO-AMERICAN MEDICAL SOCIETY.

BEFORE the war the number of British and American practitioners established in the health resorts of Europe and Northern Africa was increasing year by year, and a society formed as a bond of union flourished. This Continental Anglo-American Medical Society arranged an annual dinner in Paris and issued from year to year a corrected list of members in order to enable scattered practitioners to keep in touch with each other, especially with a view of knowing to whose care patients might be safely recommended when changing from one resort to another. Dr. Robert Turner was the diligent hon. secretary and treasurer of the Society, acting with the help of an executive committee of eight, representing different areas. The circumstances of the war, subsequent changes in economic conditions, and the stiffening of the ordinances regulating practice by foreigners have profoundly altered the outlook of practice abroad since 1914, and in reply to a circular sent out last November Dr. Turner received 32 answers—13 informing him that the members written to had either died or retired from practice, 14 in favour of the Society being dissolved, and only 5 in favour of its continuance. It has therefore been decided to dissolve the Society, the sum in hand, amounting to about Fr.500, being handed over to the British Hertford Hospital in Paris. We confess to considerable sympathy with the minority who desired continuance, and have little doubt that, if they choose to form the nucleus, the opportunity of further association will arise. Practitioners resident abroad stand in particular need of such mutual help and support.

LUNATIC ASYLUMS AS SPECIAL HOSPITALS.

Dr. J. R. Lord, in a recent lecture which has been reprinted¹ expresses frankly and with some force his view of the difficulties with which an attempt to reform the lunacy administration must contend. The first of these is the problem of reconciling the liberty of the subject with timely and adequate mental treatment. The Lunacy Act of 1890, regarded as a measure for preventing wrongful detention, is admirably framed (and, indeed, it may be said that critics who attack the present "system" from this side are attacking its most invulnerable point). But this Act, providing, as it does, that no person shall be detained before or after he is sufficiently deranged to be certified, ignores the patient's welfare at two stages of his illness when care and treatment are of the utmost importance—namely, the stages of onset and recovery. Its whole essence and object, in fact, is not therapy, but justice.

Institutions for the treatment of incipient cases on a voluntary basis are being demanded loudly, and a few exist. Dr. Lord's view is that these "within a few years will be tainted places, just as the mental hospitals are in the public estimation. Other and still more camouflaged institutions will then be called for." He would therefore utilise existing institutions for this, as well as their present, purpose, and amend, or rather revolutionise, the lunacy laws in conformity with this object. The three propositions in which the mechanism of this change is outlined are necessarily incomplete; their underlying principle is the right of voluntary admission to State asylums without formality.

The success of such a plan presupposes the removal of the existing prejudice against asylums. This is the second difficulty, and the greater. "Only a bold attempt to teach the rising generation better ideas regarding insanity will remove it. The educational code of our national schools should decree a course on both mental and physical hygiene for senior pupils, and children should all be taught that: 1. Mental disorders are as common and as natural as common

colds. 2. That mental and physical hygiene are one and the same problem, and that such terms as 'run down,' 'fed up,' and 'need a change' are descriptive of mental exhaustion, and that insanity is only a mental breakdown of a more severe character. 3. That mental hospitals are merely special hospitals for the treatment of severer forms of mental complaints. . . . 4. That superstitious views regarding insanity belong to the past. . . ." No one who believes the third article of this creed, and the majority of common-sense people do so, will quarrel with this, or deny the ultimate value of its effect, although its feasibility is another matter. An earlier and more promising start might be made by considerate instruction of the relatives of existing patients by the medical officers in charge of them. It is these people, who, by insisting on secrecy—the virtual disappearance of an insane person from the land of the living—create in any given generation the atmosphere of distrust and horror which surrounds the asylums.

People in the early stages of insanity, particularly melancholia, often do not consult doctors, and their relatives do not recognise that they are insane. Universal early treatment will only come when the general public understands something of the nature and aspects of these disorders.

COLONIAL HEALTH REPORTS.

Public Health in the Turks and Caicos Islands.

THE Turks and Caicos Islands (writes Mr. G. Whitfield Smith, the Commissioner and Acting Judge, in his report for 1921) lie between 21° and 22° N. latitude, and 71° 50' and 72° 50' longitude, and are therefore just on the edge of the tropics. The two groups are divided by a channel 21 miles in width, and the entire area is stated to be 166 square miles. The islands are distant, about 720 miles from Bermuda on the north, about 450 miles from Jamaica on the south-west, and about the same distance from Nassau, Bahamas, on the north-west. The climate is equable and healthy and rarely unpleasantly hot, owing to the strong and never-failing sea breezes. The average temperatures taken from the records of five years discloses a maximum of 90° and a minimum of 61.5° F. The rainfall for 1921 was 26.40 inches. The few cases of malaria which occur from time to time, chiefly in the island of North Caicos, and the origin of which can usually be traced to the neighbouring republic of Haiti, are of the mildest description. There are no freshwater ponds, and inhabitants of the settlements at Grand Turk, Salt Cay, and Cockburn Harbour depend entirely on rainwater tanks with which most houses are provided. Scattered throughout the islands are wells of more or less brackish water, in most cases potable by those accustomed for generations to water of this character. The estimated population at Dec. 31st, 1921, was 5612. The white population, numbering 210, is composed almost entirely of the descendants of Bermudians. The birth-rate in 1921 was 40.5 and the death-rate 19.5 per 1000. A mild outbreak of alastrim, introduced from Santo Domingo and Haiti, occurred during the year, but there was no death from the disease. The Manning Hospital (opened in October, 1918), affording accommodation for six patients in the public wards and two in the private wards, possesses a well-equipped operating theatre and is up to date in other respects.

Public Health in the Uganda Protectorate.

It is stated in the Uganda Protectorate report for 1921 that during the year there were 62 cases of blackwater fever with 15 deaths, as compared with 56 cases and seven deaths in 1920. At the venereal treatment centre at Mulago, which was opened at the end of the previous year, there were over 36,000 attendances for treatment. Observations taken at Entebbe show that the average rainfall for the last 22 years has been 58.26 inches; the average temperature for the last 18 years, maximum 78.46°, minimum 62.76° F.; and the mean daily sunshine 6 hours 34 minutes. The climate of the Protectorate as a whole, though pleasant, cannot be considered healthy for Europeans. European children, as a rule, thrive in infancy, but considerable risk is attached to bringing them out when they are over two or three years old, as they are liable to attacks of malaria and the resultant anæmia. The health of adults depends mainly on their mode of life, and with care constitutional health should not be impaired, but if physical fitness is maintained the altitude and proximity to the Equator combine to produce nervous strain after prolonged residence. Outdoor manual labour is dangerous for Europeans, and on plantations a manager's or owner's duties are for the most part supervisory. The favourite localities for European plantations are the Buganda Province (particularly the Mengo and Mubendi districts), the Toro district of the Western Province, and the Bunyoro district of the Northern Province. There are a few estates in Busoga (Eastern Province), but this area is not so popular.

¹ Lunacy Law and Institutional and Home Treatment of the Insane, being the Final of a course of Lectures on Psychiatry for local secretaries of Mental Welfare Associations, delivered at Horton Mental Hospital, Epsom.

THE
Lumleian Lectures

[ABRIDGED]

ON

ENCEPHALITIS LETHARGICA
(EPIDEMIC ENCEPHALITIS).

*Delivered before the Royal College of Physicians of
London on March 15th, 20th, and 22nd, 1923.*

By ARTHUR J. HALL, M.A., M.D. CAMB.,
F.R.C.P. LOND.,

PROFESSOR OF MEDICINE, UNIVERSITY OF SHEFFIELD; SENIOR
PHYSICIAN, SHEFFIELD ROYAL HOSPITAL.

LECTURE I.

IN choosing a title for these lectures it seemed best to retain the two names which alone have survived amongst the many suggested for this disease. The name encephalitis lethargica survives chiefly from reasons of sentiment, since it is the one selected by von Economo.¹ By retaining it we pay tribute to his remarkable work; a work rendered even more remarkable by the fact that it was carried out at the height of a great war, under all the difficulties which that involved. In this country the name is at present the one under which official notification must be made, and its temporary retention is therefore desirable in order to avoid confusion. There is, however, some danger, lest, by emphasising one symptom, it should narrow our view of the disease and lead to the overlooking of cases in which lethargy is slight in amount or even entirely absent. On the whole, the name epidemic encephalitis seems the better, and will probably be generally adopted. In these lectures the two will be used indiscriminately.

The story of its early appearances in various parts of Europe has been frequently told, but the fact that an outbreak, of considerable extent, occurred in France, coincident with that recorded in Austria by von Economo in 1917, was for some time rather strangely overlooked. Cruchet, Moutier, and Calmette,² a week or two prior to the publication by von Economo of his classic paper in Vienna, recorded a series of 40 cases of "encephalo-myelitis" at the Société Médicale des Hôpitaux de Paris. That these were cases of epidemic encephalitis is now generally recognised, but when the second outbreak occurred in France in 1918, its relation to these cases in the preceding year was for some time overlooked. As Flexner suggests, the disease travelled more quickly than the literature concerning it.

HISTORICAL.

The accounts of past epidemics contain many references to outbreaks presenting clinical features which may easily be interpreted as instances of this disease. Crookshank³ has collected most of the available information on this subject in his many valuable papers. Of the three epidemics which have been more closely associated with epidemic encephalitis, two have been thus associated by their "lethargic" characters—the "Schlafsucht," of Tübingen (1712-13) and the disease called "nona" (1889-90); whilst in the third, Dubini's electric chorea (1846), the connexion is not through this symptom, but from the muscular jerkings. This latter disease did not suggest itself as a precursor of epidemic encephalitis until after 1919, when the myoclonic type first became prominent. If these three diseases really were outbreaks of epidemic encephalitis, they failed to show the variety or the extent of spread which the present "influence" has done. Isolated examples of more or less definite cases have been found in the literature of the past century. Gayet,⁴ Bozzolo,⁵ Achard and Paiseau,⁶ Raymond and Claude,⁷ and others have published such cases.

In 1903 an apparently typical case was under my care in a boy of 11. Within two days of onset with fever, malaise, and vomiting, he had attacks of irregular breathing with dyspnoea leading to tetany. Dysphagia was also present. Right facial palsy and aphasia with jerkings in the limbs occurred next day. He was very drowsy by day and restless and irritable at night. There were incoördinate movements of the eyes and oscillations of the eyeballs "not amounting to nystagmus." Marked sweating and (?) loss of accommodation. Kernig + at one time. Recovery took place in two or three weeks, but a slight febrile recurrence occurred about six months later, and a permanent slight facial paralysis with spasmodic twitching persisted for many years. He is, however, a healthy man and saw active service in the war. In the same year, 1903, a woman attended hospital, complaining of constant sleepiness. She would fall asleep at all hours of the day whilst working or eating. This patient was lost sight of and cannot be traced.

J. A. Nixon, of Bristol,⁷⁹ has recorded a typical case in a boy, which occurred in 1908. Apart from the suggestive clinical picture, during the acute stage, the resulting Parkinsonism makes its true nature evident. Souques⁸ dates a case of paralysis agitans from a probable encephalitis in 1910. The patient was then 39 and for more than a year slept all day and had to be wakened to eat. During all this time there were rigidity and awkwardness in the left arm. The tremor did not begin until 1914.

In this connexion it is of some interest that during 1916, whilst Cruchet's cases were occurring in France, it is probable that isolated cases were occurring on the British front. In June of 1916 a soldier was invalided home, and came under my care at the Third Northern General Hospital suffering from what was then put down as an "atypical paralysis agitans." He was only 38; the face and posture, though slight in degree, were unmistakable. There was usually a fine tremor of the right arm and leg, but at times there was a coarse intention tremor. The pupils were unequal. At that time the question of a post-encephalitic residuum was necessarily not thought of. It seemed worth while to follow this case up and see what had happened. He is now in a hospital, and by the courtesy of the medical officer in charge, the following facts have been ascertained. At the present time, seven years after onset, he has "a coarse tremor of the right hand and arm, increased by voluntary effort. Some rigidity. No anæsthesia or wasting. Headache, vertigo, and broken sleep at times, and he is very excitable." It is thus evident that during these seven years he has not developed as a typical pre-senile paralysis agitans does, and the persistence and irregularity of the residua resemble cases of encephalitic origin.

In 1912 G. W. Watson, of Leeds,⁹ recorded two cases of focal encephalitis which have many resemblances to epidemic encephalitis. Small outbreaks in children, of a suggestive kind, were published by Comby¹⁰ in 1907 and Gordon¹¹ in 1913.

EPIDEMIOLOGY.

In tracing the spread of the disease to various parts of the world, it is evident that whilst its occurrence was recognised in certain places only, isolated cases of a similar kind were probably present over a much wider extent in Europe than the records of that time admitted. Frequently they were referred to as "Grippe-encephalitis," but with the advent of more definite outbreaks in later years their true character has been admitted. The most severe outbreak in Europe generally was that of the winter 1919-20, whilst in this country by far the largest outbreak was in the following winter 1920-21.

In January, 1919, the Local Government Board made notification compulsory. As a result we have in this country statistics which are unequalled either in quality or quantity by any elsewhere. The value of the reports issued first by the Local Government Board and later by the Ministry of Health, in regard to this disease, cannot be assessed too highly. They

are models of what a Government department can do to forward medical knowledge.

During successive years the official figures of notified cases in England and Wales are:—

1919	..	..	541	1921	..	..	1470
1920	..	..	890	1922	..	..	454

It is clear that the number of cases in many other European countries has been very much larger than in this country. In France it is estimated that there must have been at least 10,000 cases up to 1920, and in Italy up to April, 1920, 3900 cases had been reported.

INCIDENCE OF THE DISEASE.

Seasonal Incidence.—In most countries this has been strikingly constant. The outbreaks usually begin in November or December and reach their maximum in February or March, disappearing rapidly in April and May. This seasonal incidence was first called attention to by S. P. James¹² in 1918, and by him emphasised as a point of difference from poliomyelitis. In one or two places outbreaks have shown their maximum at other periods, but this is exceptional.

Occupation and Sex.—There is nothing noteworthy as to the incidence in different occupations or the two sexes. Statistics of large numbers show that the sexes are about equally affected (Parsons¹³).

Age.—The first series of cases published in this country in THE LANCET in April, 1918, included a woman of 70 and Harris's¹⁴ case of a new-born infant. Between these extremes the ages varied widely. This has been characteristic throughout. No age is exempt. The difference in age-incidence between this disease and poliomyelitis was also emphasised by James¹² in 1918 and his observation has been fully confirmed by subsequent events. Batten and Still¹⁵ first called attention, in this country, to the peculiar form in young children, in their paper on "Epidemic Stupor."

Race.—In Warsaw, Sterling¹⁷ found the case-incidence in the Jewish population much greater than amongst the Christians.

Case-mortality.—The case-mortality is high. The figures vary in different countries. In England and Wales the official figures are: 1918, 22 per cent.; 1919-20, 48.3 per cent. In most other countries the figures come from the records of individual observers only, and these vary widely. On the whole, the average appears to be something over 25 per cent. This figure is much smaller than that of the case-mortality in this country. The difference is possibly due to the varying inclusion, or exclusion, of mild cases (*formes frustes*). In official statistics many of these are probably absent, as they are not notified, whilst individual observers, on the look-out for such cases, miss none. There seems no evidence, except the official figures, to suggest that the disease has been more severe in this country than elsewhere; indeed, judging from the literature, the reverse seems more probable. The mortality, according to Parsons,¹³ is high in the first five years of life—lowest at about 10 to 15—then rises with each decade, until in the seventh it is 80 per cent.

Pregnancy.—Judging from the number of recorded cases it appears as though pregnant women were particularly susceptible to this infection. Whether this is really so or not, is difficult to prove. There is some evidence that in women who have suffered from an attack, the occurrence of a subsequent pregnancy seems to precipitate the onset of later manifestations. It may occur at any period of pregnancy, but usually towards the end, rather than early. There seems to be no particular tendency to abortion. The mortality is thought by many to be higher than in other cases. The official statistics of this country do not confirm this. The question of whether or not to empty the uterus, either by induction of labour or Caesarean section, is very difficult to answer. The evidence on this point is, as yet, contradictory. Personally, I

have seen induced labour followed by death, and Caesarean section, even under most adverse conditions of persistent hiccup, completely successful—a healthy child was born and the mother recovered. The effect on the child will be dealt with under contagion.

CONTAGION.

The rarity of any evidence of contagion has been noted in every country and in every outbreak which has occurred. There is, however, evidence from three sources that contagion may occur, at times to a marked degree. These sources are: (a) Outbreaks occurring in institutions; (b) mothers infecting new-born babies; (c) more than one case in household, nurses attending cases, &c.

(a) Of the first group three striking examples have occurred. The first was in August, 1919, at a girls' home at Derby, investigated by MacNalty and fully recorded in the annual report of the Ministry of Health, 1919-20. Twelve cases occurred amongst the inmates within two weeks, with five deaths. The true nature of the disease was proved by pathological and experimental investigations with material from a fatal case, carried out by McIntosh and Turnbull.^{18 19}

The second outbreak was reported by Krause²⁰ in July, 1922. The date of its occurrence is not stated. This, also, took place in an institution for girls, in the Lower Rhine district. Ten who slept in the same room were taken ill with dysphagia, dyspnoea, diplopia, and paralysis of accommodation. Nine died within two and a half days. Thirteen other inmates became ill some days later, four of whom died. The doctor attending them was similarly affected eight days later. The pathological investigations had not been completed at the time of publication, but no other obvious cause was found post mortem. Food poisoning, which had been suspected, was positively excluded.

The third was recorded by Fyfe.²¹ It occurred in September and October, 1922, at a village school for girls in Warwickshire. Four scholars were affected—there were no deaths. The attacks were of lethargic type and ambulatory. In three cases there were definite mental residua.

Two striking features of these three epidemic outbursts of intense contagion are, that all occurred in institutions for young females, and, that in two, certainly, they appeared at periods when no general outbreak of the disease was occurring in the neighbourhood. The exact date of the Rhenish outbreak is not given. It was reported to the Cologne Society in July.

(b) The number of cases in which children born of parents suffering from the disease have become infected is quite considerable. Harris,¹⁴ Pirie,¹³ Montgomery,¹³ Legge,¹³ Mercier Andrieux and Bonnaud,²² Santi,²³ and others have recorded such cases. In a case seen by Novaes e Sousa²⁴ myoclonus was present in the baby during parturition. Experimentally also Levaditi, Harvier, and Nicolau²⁵ have succeeded in transmitting their virus, obtained from human encephalitis through a pregnant rabbit to the central nervous system of a fetus rabbit in utero. In Hallé's²⁶ case the mother began with encephalitis whilst suckling a healthy four months' baby. She declined to wean it. The baby began to be ill nine days after the mother, and died in five days; the mother recovered.

(c) Of other isolated cases—Buzzard and Greenfield²⁷ saw mother and son affected within 17 days, De Laroche²⁸ wife and husband within a month, Reece²⁹ and Lortat-Jacob³⁰ nurse and encephalitis patient, Roger and Blanchard³¹ two soldiers in neighbouring beds, Netter³² three children sleeping in same room. The fact that such cases are thought worth recording is the strongest testimony to the general absence of contagion.

Kling, David, and Liljenquist³³ in an intensive study of an epidemic in the Swedish province of Wilhelmina found a large number of incomplete cases in the households where the full form of encephalitis cases occurred. Some of these had

evidences of nervous complications, others had merely slight generalised malaise. In two houses all the inmates were infected with one or other form of the disease.

DURATION OF INFECTION.—INCUBATION PERIOD.

There is some evidence, both clinical and experimental, that contagion may persist for a very long time. Netter,³⁴ Lemierre,³⁵ and others have recorded such cases. As a rule, the contagion seems to light up with a recrudescence of the disease, which may be after an interval of many months. Experimentally Levaditi, Harvier and Nicolau,²⁵ and others find that their virus can be preserved active for many months, whilst Netter, Cesari, and Durand³⁶ obtained a positive result in a rabbit from the nervous system of a case fatal after 15 months, and Kling³⁷ from the cerebro-spinal fluid of a post-encephalitic Parkinsonian of 18 months' duration. The clinical occurrence of "recrudescences" is a well-recognised characteristic of the disease. The long duration of infection adds considerably to the difficulty of any kind of preventive isolation.

From such data as are available Parsons¹³ concludes that the incubation period may be from one day up to two weeks or even more. Kling and Liljenquist³³ from three of their cases think that ten days is the average period, and in Hallé's case²⁶ this was so.

EPIDEMIC HICCUGH.

Although the occurrence of hiccough in epidemic encephalitis was noted by von Economo¹ in 1917, and by Lord³⁸ at Colwyn Bay in 1918, the actual epidemic of febrile hiccough did not begin until the late autumn of 1919—almost coincidently with the first appearance of the myoclonic type of encephalitis. Cases were reported from various parts of Europe and also from Winnipeg (Boyd³⁹), where at least 50 cases were seen preceding an outbreak of encephalitis. During the winter of 1920-21, these hiccough epidemics recurred to a considerable extent in various parts of Europe, France, Italy, and Switzerland particularly. In this country they were also seen, but only in comparatively few numbers and scattered areas. The hiccough is usually rather severe, lasts for a few days, and is often accompanied by slight feelings of malaise, headache, feverishness, and perhaps catarrhal symptoms. It may be more severe, and even distressing, persisting for a week or two. It is usually intractable.

Infectivity.—There is abundant evidence that it is contagious. In all countries where it has appeared, cases, in which contact with a case has led to infection, have been repeatedly recorded. In this country Farrar¹³ traced direct contact in a series of eight cases. Doctors attending cases have themselves suffered. Nor has it entirely disappeared. During February, 1923, I saw three cases in one household, one of which persisted violently for a fortnight. Other cases have also been reported during the last few weeks in the Midlands.

Relationship to Encephalitis Lethargica.—Lemoine⁴⁰ in France, and Farrar¹³ in this country have recorded cases in which contact with a case of epidemic hiccough has been followed by a typical attack of encephalitis lethargica. Dargein and Plazy⁴¹ saw a man who, beginning with what appeared to be a simple case of epidemic hiccough, which lasted for 18 days, recovered, but about two weeks later developed a typical oculo-lethargic type of encephalitis. Dufour,⁴² Clerc Foix and Mercier des Rochettes,⁴³ and others have reported similar cases. Some are of opinion that the two conditions are identical. Bing and Staehelin⁴⁴ include "singultus epidemics" in their statistics of encephalitis, as one of the rudimentary forms: Lhermitte⁴⁵ speaks of *Le Hoquet épidémique: forme singultueuse d'Encephalite épidémique*. This, however, seems at present a matter of uncertainty and there are difficulties in accepting such a generalisation. Rosenow and Jackson,^{46 47} from their experimental work on epidemic hiccough,

believe that it is due to a non-filtrable coccus of the pneumococcus-streptococcus group. If this work is confirmed, it is difficult to correlate with the filtrable virus of epidemic encephalitis described by Loewe, Hirschfeld, and Strauss,⁴⁸ Levaditi, Harvier and Nicolau,²⁵ and others. At the present time no dogmatic statement on the relationship of the two conditions seems warranted.

RELATION OF EPIDEMIC ENCEPHALITIS TO OTHER EPIDEMIC DISEASES.

The controversies which in the early days raged around its relations to poliomyelitis have now subsided. They were at that time very natural. Many whose experience of the latter disease was very wide and whose opinions were weighty, inclined to the identity of the two. It is mainly, however, in the varying after-results that the two differ so widely, and on its first appearance such after-results were necessarily unknown. The residua of poliomyelitis are practically limited to greater or less permanence of the original paralyses; in epidemic encephalitis such paralyses form a relatively, and unexpectedly, small percentage of the many and severe residua.

The relation to epidemic influenza or "grippe" was not seriously considered in this country, or in Vienna, or France, on the first appearance of encephalitis, because there was then no concurrent epidemic of influenza, and because the symptoms of epidemic encephalitis and its mode of spread were so entirely different from those familiar in epidemics of that disease. In various countries, however, the identity of the two was for some time upheld with much tenacity. This view seems to be gradually weakening even in the most powerful of its strongholds. As time goes on the difference between the two diseases becomes increasingly marked.

Although the evidence appears sufficient to warrant considering epidemic encephalitis as a separate disease, its possible relationship to other epidemic diseases cannot be ignored. That it did appear at or about the same time as an epidemic of influenza of great severity and extent might be merely a coincidence, but seeing that outbreaks, the descriptions of which are so similar in many respects to those recently seen, have, in past times, been recorded in more or less close connexion with waves of epidemic influenza, the probability of some relationship is considerable. What is the nature of that relation has not yet been satisfactorily explained.

There are those who from an epidemiological standpoint would group together influenza, cerebro-spinal fever, polio-encephalitis, poliomyelitis, and epidemic encephalitis as arising from some common condition. According to this point of view, it would seem that could the waves of pandemic influenza be abolished, it is possible that the epidemics of the other above-mentioned diseases would disappear also; that whilst these "satellite influences" are not identical in form with influenza they are so nearly related to it that without its help they would not be potent factors in producing disease. There is much to be said from this point of view, and it may be that in generations to come, when further experience has accumulated, the exact relations in which these diseases stand to each other may be more intimate than is now generally believed. Possibly there may be some common factor in the constitution of the hosts or some associated change in physical conditions which renders many usually harmless parasites capable of becoming dangerous and destructive enemies to man at certain periods of time. Meanwhile, the more accurate knowledge of the individual components of these epidemic scourges would seem to be essential in approaching the ideal of preventing their occurrence.

The relation of epidemic encephalitis to the Australian X disease which appeared in that country in 1917-18, seems doubtful. Cleland and Campbell⁴⁹ consider that the two are widely separated both on clinical and experimental grounds. Breinl⁵⁰ and Flexner⁵¹ incline to the view that it was an aberrant form of poliomyelitis.

PATHOLOGICAL ANATOMY.

The earliest findings by von Economo and von Wiesner¹ in Austria, in May, 1917, were soon followed by those of Marie and Tretiakoff⁵² in Paris, in May, 1918, and of Marinesco¹² in this country, in October of the same year. Since then their findings have been repeatedly confirmed by pathologists in every country where fatal cases have occurred. There is indeed a definite recognised histopathology of the fully developed disease. Buzzard and Greenfield²⁷ called attention to the occurrence of "meningeal hæmorrhages." Bramwell and Miller⁵³ found a surface hæmorrhage over the cerebellum. The general histologic picture has been frequently described and is familiar. The perivascular cuffs of variable thickness and extent, the changes in the nerve cells and glial proliferation, the tendency to localisation in the grey rather than the white matter, and chiefly, but not exclusively, in the mesencephalon and basal ganglia. Kinnier Wilson⁵⁴ speaks of the "peri-aqueductal grouping." Other parts may, however, be affected—the cortex, the cord, nerve trunks, and ganglia.

MINUTE GRANULAR BODIES.

Da Fano and Ingleby⁵⁵ in 1919 described minute granules in the protoplasm of certain groups of nerve cells from fatal encephalitis cases. Da Fano,⁵⁶ in further investigations, found them both within and without the nerve cells, and also in salivary glands. Hume, Nattrass, and Shaw⁵⁷ saw them in four fatal cases. More recently Da Fano,⁵⁸ working with the virus of herpes febrilis, has found similar bodies in the brains of rabbits infected with this virus. Encephalitic neuro-corpuscles have also been described by Levaditi, Harvier, and Nicolau²⁵ in experiments with their virus of encephalitis. Da Fano believes that these are identical, morphologically, with the structures he finds in herpetic meningo-encephalitis.

LECTURE II.

CLINICAL SIGNS AND SYMPTOMS.

Epidemic encephalitis is characterised by three striking clinical features: (a) its polymorphism, (b) its irregular progress, (c) its many and peculiar after-results. The irregularity of its progress, by fits and starts (von Economo's *schubweise*), makes the separation of sequelæ from recrudescences almost impossible.

Onset.—Classification.

The onset may be sudden or gradual. Sometimes the suddenness is extreme. Apoplexy (Boyd³⁹), epilepsy (Guillain⁵⁹), syncope (Schmidt⁵⁹), vertigo, headache, or other pains may, any one of them, appear "like a bolt from the blue." Such stroke-like onsets are not the most common. As a rule, however, the day of onset, sometimes even the hour, can be definitely stated. One of my patients went to bed perfectly well; on waking next morning he saw double, fell over on trying to get up, and talked incoherently. A little boy was playing in the snow in the afternoon and by tea-time was lethargic and feverish.

The onset may take various forms—general malaise with headache and fever, simulating epidemic influenza, slight delirium at night. Vomiting, and occasionally diarrhœa, sometimes of considerable obstinacy. Hume, Nattrass, and Shaw⁵⁷ saw acute diarrhœa at onset in a fatal case. Constipation, however, is more common. Drowsiness of varying depth, and usually increasing, may be the first symptom. Such cases may remain ambulatory for long periods or even throughout. Diplopia, with or without lethargy, is common. Other cranial or limb palsies may occur at onset. General extreme asthenia, acute mental symptoms, mania, delusional insanity, confusional states, a delirium tremens-like condition, or excito-motor phenomena of all kinds may be the first evidence of disease. Edwin

Bramwell⁵³ called attention to the onset with severe neuralgic pains in the head or limbs. When the pain is abdominal the simulation to an acute abdomen may be very close.

No completely satisfactory method of classification has yet been made. The plan suggested by MacNalty,¹² and adopted, with the additions suggested by Walshe,⁶⁰ by the Ministry of Health has the advantage of simplicity and convenience.

GENERAL SYMPTOMS.

Fever is usually present, but, as a rule, does not play a prominent part in the disease. Hyperthermia is occasionally seen, even as high as 111° F. in a case reported by Gelpke,⁶¹ which recovered. In one of my cases the temperature reached 107.5° at death. Headache is a frequent symptom and often persistent. Usually there is nothing characteristic about it. Lethargy in some degree and at some period or other is the rule. Graham Forbes⁶² found it in 126 out of 130 cases. It varies in character and degree. It may be light and the patient knows what is going on around, but cannot rouse himself. In many, apparently asleep, one is surprised by the quickness of the reply to a question. In others the reply is unduly delayed. The sleep, however, may be much deeper than this and waking not easy. In such patients the period of lethargy may be a complete blank in their minds afterwards. The desire to sleep may be irresistible and occur at any moment.

Duration of Lethargy.

Lethargy may last for days, weeks, or, in rare cases, months. It may disappear and recur at long intervals. In one of my cases, a girl of 15, attacks of lethargy recur about once a month. Each lasts for a few days only. This has continued for five years. Netter has described a case in which lethargy appeared first 12 months after the onset of encephalitis. It may be absent throughout, even when ocular palsies are present.

Theories as to Cause of Lethargy.

Five possible views as to the cause of lethargy have been brought forward.

1. Buzzard⁶³ thinks that it may be due to increased intraventricular pressure, caused by the acute changes around the aqueduct of Sylvius.

2. MacNalty¹² suggests an extension of inflammation from the region of the third nerve nuclei to neighbouring afferent paths, thus interfering with stimuli to the thalamus.

3. Disordered hypophyseal function, leading to hypopituitarism, has been suggested on the grounds that lethargy is a symptom of this defect and that polyuria, obesity, and even Fröhlich's syndrome have followed encephalitis.

4. Marinesco⁶⁴ considers the lethargy as a part of the marked tonus changes which are so often present.

5. Abrahamson⁶⁵ looks upon a poisoning by the virus of the psychic synapses as causing the various stages of sleep in a gradual series from drowsiness at the one end to coma at the other.

As regards the question of hypopituitarism, no definite or sufficient pathological changes in the hypophysis have as yet been found in these cases to support this view. At present the data are insufficient for arriving at a conclusion as to the cause of lethargy.

Hyposomnia.

Hypo- or in-somnia may persist throughout. Laporte and Rouzaud⁶⁶ record such a case which was fatal on the eleventh day. More frequently it alternates with lethargy, either preceding or following it. Nocturnal insomnia will be referred to later. All agree that when present it is very intractable.

LOCALISING SYMPTOMS.

These are so numerous, seeing that any part of the nervous system may be involved, that it is only possible to refer to certain outstanding features.

The ocular disorders are almost entirely limited to the muscular actions. Changes in the optic nerves, though recorded, are rare. As a rule these muscular changes are, as Lhermitte pointed out, rather a disturbance of muscular synergy than definite strabismus,

although the latter may occur. Nystagmiform movements, or even irregular jerks of the eye muscles, are frequent. Paresis of conjugate movements is often seen. Incomplete bilateral ptosis, somewhat like an exaggeration of the "lids heavy with sleep," is often associated with lethargy and may persist. Pupillary disorders of every kind and in almost every combination have been observed. Argyll Robertson pupils with loss of knee-jerks was first recorded by Naef⁶⁷ at Munich in 1919. Jewesbury⁶⁸ recently showed such a case at the Royal Society of Medicine. Bilateral paralysis of accommodation is not uncommon. Genet⁶⁹ thinks that this, with intact light and convergence, is a valuable sign, and that it differs from other forms in its sudden onset and curability. The fifth and seventh nerves are both frequently involved. It is not unusual to find a facial diplegia. In one of my earliest cases this was the only symptom throughout. It disappeared completely. Weakness of the masticatory muscles is common; in some cases there is complete "diplegia masticatoria" for a time. The hypoglossal is often affected. Hemiatrophy of the tongue may persist as the only evidence of past disease.

Positive symptoms in connexion with all these cranial, as well as other nerves, are common. More commonly they occur as later manifestations, and will be dealt with elsewhere. In the tongue region they may be exceedingly troublesome. André-Thomas and Jumentiet,⁷⁰ Christin,⁷¹ and Byschowski⁷² have recorded such cases. In Schmidt's⁷³ case the tongue was rigidly projected over the teeth, necessitating surgical measures to give relief. Another feature of the cranial palsies is their temporary character and the tendency to shift from one nerve to another or from one side to another.

Dysphagia.

This occurs frequently. Many spasmodic affections of the pharyngo-laryngeal region are also seen. In a certain number of these the similarity to rabies is very close. In October, 1918, I saw a case of this kind. The attacks of laryngeal spasm were frequent and of great intensity, the patient becoming cyanosed and unconscious in them. Tracheotomy was performed and gave relief. Any attempt at swallowing set up the spasm at once. The attacks passed off in a few days but were followed by other nervous symptoms. Similar cases were recorded by Denyer and Morley⁷⁴ in 1920, and by Kahn Barbier and Bertrand,⁷⁵ and Sarkies⁷⁶ in 1921. In a fatal case typical changes were found in the medulla and cervical cord. These cases call to mind those recorded in past epidemics, quoted by Crookshank³ as "hydrophobia-without-the-dog."

Positive Excito-motor Phenomena.

Although positive excito-motor phenomena were present in isolated cases during the first outbreak, they then held no prominent place in the clinical picture. Amongst von Economo's first series, choreatic unrest and choreatic jerkings occurred in two cases, and Cruchet² also noted their occurrence. In January, 1919, Poynton¹⁴³ showed a myoclonic case in a child of 2, which began in the 1918 outbreak. It was not, however, until the epidemic of 1919-20 that they became predominant. Sicard and Kudelski¹⁰³ in Paris, and later Boveri,¹⁰⁴ called attention to the prevalence of so-called myoclonic types of the disease, whilst in this country Ellis¹⁰⁵ and others recorded similar cases. Since then large numbers have been seen in all parts of the world. In their more severe forms they present a very strange picture. The only case of this extreme type amongst my series occurred in December, 1919. Headache and pains in the neck occurred for the first week or two, then jerkings of extreme violence affecting chiefly the neck and shoulder muscles, causing extreme pain, associated with persistent insomnia and ending fatally. Lethargy was absent throughout. No autopsy was allowed. In this case, as in others recorded, the explosive speech was a notable feature.

Chorea-like movements have been frequently seen in later outbreaks. Stertz¹⁰⁶ reports that 50 per cent.

of his cases in Munich during the 1920 epidemic were of this type. In most cases the terms choreatic or choreatiform movements are used signifying that whilst like cases of Sydenham's chorea, they are not, as a rule, quite the same. That has been certainly so in most of the cases I have seen. The simulation of chorea may, however, be extremely close. In June, 1918, a boy of 16 was admitted to hospital with what was apparently chorea gravis. He was occasionally noisy and delirious at night; there was no heart lesion. Temperature normal; respirations 24 to 36. He became steadily worse and died three weeks after admission. The history showed that he had begun to feel ill about a month before, lethargy being marked for several days. Twitching and delirium kept recurring at intervals a fortnight after onset. Looking at the movements alone in this case they were indistinguishable from those of Sydenham's chorea. From the history it was obviously encephalitis lethargica.

Paralysis of all kinds may occur, hemiplegias, monoplegias, paraplegias, crossed hemiplegias. Buzzard and Greenfield²⁷ were the first to call attention to hemiplegia in all its forms as being of this origin. Permanent flaccid palsies may result, but compared to their frequency after poliomyelitis they are relatively rare in this disease. Polyneuritis affecting chiefly the legs is not very common. The three cases which I have seen all recovered, two completely.

Myasthenic Type and Cerebellar Type.

Cases simulating myasthenia gravis have been recorded. The first case of encephalitis which came under my notice in 1918 was of this type. Grossmann⁷⁷ has recently recorded three such cases.

Fragmito⁷⁸ and others have recorded cases showing definite cerebellar symptoms, and Marinesco¹² in 1918 found anatomical changes in the cerebellum of a fatal case.

The Reflexes.—Fits.

The changes in the reflexes necessarily vary with the location of the morbid process in the central nervous system. The cases with loss of knee-jerks and fixed pupils have been referred to above. Kernig's sign may be present in the acute stages of meningitic type.

Fits of epileptic type are not uncommon. They may occur at onset, during the illness, or as an after result. In one of my cases a little boy whilst convalescent in the third week suddenly had a series of fits with rise of temperature, which lasted only a few hours. He then continued his interrupted recovery. Edgeworth,⁷⁹ of Bristol, has recorded a similar case.

Hypertonus.—Katonus.

Both of these are common symptoms. In a case reported by Davis,⁸⁰ in which the arms were firmly flexed, they were extended under anaesthesia and fixed in extension. On removing the splints the arms were equally fixed in extension and could not be straightened. Petren⁸¹ speaks of a case in which the hypertonus was so great as to simulate paralysis.

Trophic.—Parotitis.

Bedsore are not uncommon, particularly in cases associated with incontinence. Severe acute wasting has been recorded by MacNalty and others. It is not rare in some Parkinsonians.

A certain number of cases have been recorded in which bilateral parotitis was an early symptom. Grenet⁸² recorded the first case of this type in 1918. In 1919 such a case came under my notice. Mumps was suspected at first, but later typical symptoms of epidemic encephalitis appeared and the true nature of the disease was confirmed pathologically. Early sialorrhoea is seen occasionally.

Skin.—Polyuria.

Unfortunately no diagnostic rash occurs in this disease. Erythematous and at times purpuric eruptions occur, but there is nothing constant or characteristic about them. The occurrence of "greasy face" (Salbestriken) was noted by Cohn,⁸³ v. Sarbo,⁸⁴ Stern,⁸⁵ and others. Herpes febrilis seu labialis is not common. Herpes zoster has been observed.

Polyuria has occurred in a considerable number of cases. It usually begins from the third to the seventh week, somewhat suddenly. It often ends suddenly also. In Benard's⁸⁶ case as much as 19 litres was passed per day.

Hæmorrhagic Syndrome.

From time to time a hæmorrhagic tendency has been noted. Buzzard and Greenfield²⁷ called attention to meningeal hæmorrhage, and hæmorrhagic cerebro-spinal fluid has been several times observed since. Naish recently had such a case under his care at the Sheffield Royal Hospital. Purpuric eruptions have also been reported by Roger⁸⁷ and Rathery and Bonnaud.⁸⁸ Netter described a case of intestinal hæmorrhage; Bassoe⁹⁰ and Eschbach⁸⁹ saw severe epistaxis, and Petit⁹¹ recorded *sueurs de sang*, occurring in paroxysms on the face. Quite recently Tinel and Dupouy⁹² have reported two fulminating cases, one with fatal hæmatemesis, another with terminal nasal, buccal, and intestinal hæmorrhages. In each there were multiple ecchymoses. Since then Douzelot and Krebs⁹³ saw a similar fatal case with severe gastrointestinal bleeding, hæmothorax, and an extensive purpuric rash.

EXPERIMENTAL WORK.

In 1919 Strauss, Hirschfeld, and Loewe,⁹⁴ in New York, succeeded in obtaining positive results in the monkey and rabbit from intracerebral inoculation of central nervous system emulsion from a fatal case of encephalitis and also from naso-pharyngeal washings from a non-fatal human case. There was some tendency to hæmorrhagic lesions. Later, in 1919, McIntosh and Turnbull,¹⁹ in this country, obtained positive results in the monkey from brain emulsion of a fatal case in the Derby outbreak. These results were obtained by intracerebral and intraperitoneal routes. In 1920 Loewe and Strauss⁹⁶ described, in connexion with their virus, a filtrable organism obtained from the brain, naso-pharynx, spinal fluid, and blood of a human case. They also found that their virus could be preserved in 50 per cent. glycerine, and passed through many series of animals.

In 1920 Levaditi, Harvier, and Nicolau,²⁵ at the Pasteur Institute, began the publication of their successful experiments on the virus of encephalitis. This work, which has been continued up to the present time, has, incidentally, given rise to so much other work in various fields of research, and led to such suggestive results, that it necessitates careful consideration. Their first successful results were obtained, as were those of Loewe and Strauss, and McIntosh and Turnbull, from brain emulsion from a fatal human case. This strain is spoken of as "virus C." Besides this, they obtained positive results from a human naso-pharyngeal swab, which they call "virus fixe." So far as they can ascertain, these two viruses are identical. Both give positive results in rabbits, either when inoculated directly into the cerebrum, or when applied to the previously abraded cornea in the rabbit. The latter is spoken of as the corneal route. These have been carried on in series for many months.

The incubation period by the intracerebral route is 4 to 6 days, by the corneal route 8 to 12 days. Enucleation of the infected eye after 24 hours does not prevent the onset of encephalitis. The incubation period can be reduced by the administration of narcotics. The changes are always found in a particular area of the brain, which they call the elective zone, and is not the same as that affected in rabies. There are two stages in the process, one acute, polymorphocytic, and of short duration, the other more chronic, and mononuclear.

Individual rabbits vary considerably in susceptibility to the virus. McIntosh⁹⁷ has recently confirmed the diagnostic value of rabbit inoculations in cases of epidemic encephalitis. He finds that basal nuclei emulsion is usually positive, whilst cerebro-spinal fluid gives positive results in about 25 per cent. of the cases. He lays stress on the site affected, the nature of the cells, and the foci in the brain.

Properties of Virus.—Human Salivary Virus.

Levaditi and his fellow-workers find that their virus has a selective affinity for nerve cells, can be preserved in glycerine solution or in a dry state for very long periods, and remains active in milk at ordinary temperature for at least 96 days. It is effective in 1/1000 saline, but innocuous in 1/10,000. Of various antiseptics, potassium permanganate 1/1000 destroys its activity completely in vitro. They did not obtain any positive results from the blood, salivary glands, or spinal ganglia, thus differing from the results in rabies and poliomyelitis respectively.

In further investigations it was found that the saliva from healthy human mouths is also capable of producing positive results, closely similar to those obtained with encephalitis virus, when applied to the rabbit's cornea. In this case, however, no encephalitic changes follow. The virus is keratogenous only. It is filtrable and so far as can be ascertained not due to a recognisable organism. It is only found in the mixed saliva of the mouth and not in the parotid secretion as it issues from the gland. It appears to be in some sort of connexion with the mouth epithelium. These findings are confirmed by Doerr and Schnabel,⁹⁵ and others.

Virus of Human Carrier.

On May 7th, 1921, Levaditi, Harvier, and Nicolau²⁵ obtained from the mouth of a healthy man who had been in contact with cases of encephalitis, a virus which differed from the above salivary virus in that it produced encephalitis as well as keratitis. Indeed, it behaved in every way, biologically and in its effects, like their original virus C and virus fixe; they therefore believe that the existence of carriers, as in poliomyelitis, is experimentally demonstrated.

At this stage of their work there were thus four available viruses: (1) virus C; (2) virus fixe from cases of human encephalitis; (3) salivary virus from human mouth, keratogenous only; and (4) salivary virus of carrier, keratogenous and encephalitogenous, like (1) and (2).

Virus of Herpes Febrilis.

Meanwhile other workers, Blanc and Caminopetros,⁹⁸ recalling the work of Grüter in 1913 on the virus of herpes febrilis and its similarity to the results obtained by Levaditi and his fellow-workers, began to study the properties of this herpetic virus. Grüter⁹⁹ had successfully transferred human corneal herpes to the rabbit's cornea, and these experiments had been confirmed by others. Levaditi, Harvier, and Nicolau²⁵ also find that this herpetic virus has close relations with the virus of encephalitis and the salivary viruses, so that it is possible to place the five in a regular series. Perdrau¹³ in this country, working with herpetic virus, confirms the transmission in series, the absence of bacteria and the preservation in glycerine solution, and Da Fano,⁵⁶ working with the same virus, confirms many points of similarity with the virus of encephalitis.

According to Levaditi, Harvier, and Nicolau, encephalitis lethargica is due to a filtrable specific agent—the ultra-virus of encephalitis. This virus may exist in at least three forms: (a) In the mixed saliva of healthy persons. It is attenuated, has an affinity solely epitheliotropic and its power is solely keratogenous. (b) In the vesicles of herpes febrilis (labialis). Here it is more virulent; compulsory epitheliotropic, but a facultative neurotropic. (c) In the saliva of carriers and in the naso-pharynx and central nervous system of encephalitics. This is very virulent, and an obligatory epitheliotropic and neurotropic.

LECTURE III.

PROGNOSIS.

Whilst in most acute diseases prognosis concerns chiefly the question of life or death during the attack, in the case of epidemic encephalitis it does not end there, but includes the almost equally important

question, Will the recovery be complete, or will something be left behind?

Prognosis as Regards Life.

The case mortality is high, probably something over 25 per cent. The most fatal period is the second week, about the eighth day. Of 135 fatal cases, collected from the literature, in which exact dates of onset and death are given, 15 per cent. died in the first week, 34 per cent. died in the second week, 15 per cent. died in the third week, 13 per cent. died in the fourth week, and 23 per cent. died later than the fourth week. The earliest fatal case was on the second day. Sudden death is by no means uncommon, especially when the medullary region is involved.

Prognosis in Various Types.

It is not possible to lay down any very definite rules for guidance. Just as it is difficult to classify this protean disease, so it is correspondingly difficult to prognose from early symptoms.

Mode of onset: Smith,¹⁰¹ U.S.A., suggests that a sudden onset is more grave than a gradual one. In this connexion, so much depends on the interpretation of the word "sudden." It is certain that severity of onset is no sure guide to prognosis. Cases with severe onset recover, and cases of mild and insidious onset end fatally.

Lethargy is thought by some to be of serious prognosis. Pecori¹⁰² finds a high mortality in his "soporose" cases. The term lethargy, however, is so wide, that without qualification it is of little value. Severe lethargy at onset is not necessarily of bad prognosis. On the other hand, lethargy which begins gradually and deepens day by day, is of serious import, especially if accompanied by rising temperature, profuse sweating, and incontinence, as was emphasised by Edwin Bramwell.⁵³ Gelma and Hanns¹⁰⁰ think the prognosis is better when sleep is light and waking easy.

Early stuporose lethargy in young children with meningitis-like symptoms is, in my experience, of serious import. The prognosis in cases of excitomotor type is very uncertain. When the "myoclonic" cases were first observed in 1919-20, by Sicard and Kudelski,¹⁰³ Boveri,¹⁰⁴ Ellis,¹⁰⁵ and others, the mortality amongst them was very high. Since that time similar cases of less severity have been common, and the gravity of this type as regards life is not so serious as was at first thought. Choreatiform types also may present any degree of severity. Severe delirium is a symptom of serious omen (Bassoe,⁹⁹ Pecori,¹⁰² Bonhoeffer,¹⁰⁶ and others). Cramer¹⁰⁷ thinks that insomnic cases are graver than lethargic.

Parsons¹³ from the official records finds that cases of generalised type without localisation (Type I.) are more fatal than other types. All are agreed that in few diseases is prognosis as regards life more uncertain and in none is it necessary to be more guarded.

Prognosis as Regards Complete Recovery.

Epidemic encephalitis has separated itself clearly from other infectious diseases by its numerous and peculiar later manifestations or residua. These are often so characteristic as to be retrognostic. "By their fruits ye shall know them" applies aptly to this disease. Many of these are so late in appearing that the percentage of them is an increasing one. They may be classified into (a) other residua, (b) Parkinsonism. The former may be considered under seven headings:—

(a) Other Residua.

1. *Mental Residua.*—These range from mere psychasthenic conditions to acute mania, sometimes of a most violent kind. In order to ascertain to what extent mental cases requiring certification had occurred as a result of this disease in England and Wales, I made inquiry from all the public asylums on this point. Thanks to the courtesy of those in charge, the following figures have been obtained.

Replies were received from 100 out of 111 asylums in England and Wales. In 80 of these no cases attributed to encephalitis lethargica had been admitted. In 20 asylums, 30 cases only had been admitted since 1918—when the disease was first recorded in this country. Of these 30 cases, the sexes were equally divided. Nine were under 20 years of age, 14 were over 30 years of age. In most of the cases (19) the attack of encephalitis occurred in 1920 or 1921. Six died, 12 recovered; in 9 there is no improvement; 7 of these are over 30 years of age. The types varied widely. The confusional and stuporose types appeared to run the most favourable course. It is gratifying to find that in this country, at any rate, the amount of mental disorder due to encephalitis and necessitating certification is not considerable.

2. *Moral Changes.*—If, however, the asylums do not see much of the ravages of this disease, the homes of the patients and even the police courts for juvenile offenders tell a different story. Whilst in adults "residua," in the form of "not the man he was before," "unable to concentrate," and so forth, are common, it is in the juvenile cases that moral changes are seen most markedly. The good child becomes a naughty child, the clever child a dunce! Restlessness, irritability, amounting to paroxysms of temper, greediness, aggressive behaviour, and morbid sexual tendencies are common results. In more severe forms thieving, suicide, and even homicidal tendencies have been recorded.

Cameron,⁶⁸ from the clinical point of view, and Shrubbsall,⁶⁸ from that of the medical school officer, have made it clear that many of these cases are merely exaggerated examples of the "difficult child," and that firm and judicious handling brings about marked improvement. This is no doubt true, but it must not be forgotten that the particular child has only become "difficult" since its illness, that it has often been a very "easy" child previously, and that the domestic machinery cannot readily be adjusted to meet such a change of disposition, especially when it coincides with convalescence from an alarming illness.

Many of the cases are, however, altogether beyond parental control. Auden,¹⁰⁸ Paterson and Spence,¹⁰⁹ and others have recorded such cases, more than one of which has reached the police courts. It thus becomes a medico-legal problem of considerable importance. In one of my cases the boy who was previously a clever scholar is now so aggressive and difficult that it is impossible for him to retain any situation.

3. *Nocturnal Excitement in Children.*—This peculiar residuum is very widespread. Pfaundler¹⁴² was the first to record a series of cases in Munich in 1920. Since then many cases have been seen in other parts. Happ and Blackfan¹¹⁰ reported many in America; Morley Fletcher,¹¹¹ Findlay and Shiskin,¹¹² Paterson and Spence¹⁰⁹ in this country. It may begin early in the disease or only after a considerable period of time. Towards evening, sometimes with remarkable punctuality (Marie and Lévy¹¹³) a change comes over the child. It becomes restless, excitable, and unmanageable. At bedtime this becomes worse and there is no suggestion of sleepiness. Sometimes the child sings, whistles, or makes queer noises, gets out of bed and runs about, until the morning is well advanced. It then falls into a heavy sleep which may last until midday. On waking, as a rule, all the excitement has passed off, and the child may appear almost normal during the afternoon, only to go through the same trouble as evening approaches. The condition is quite intractable to ordinary therapeutic measures and may persist for many months. It is spoken of occasionally as an inversion of the sleep-rhythm. This description is somewhat misleading. It is not merely that the hour of sleep is altered, but there is a definite mental excitement recurring each evening; this continues through the night, until the nervous centres are exhausted and the

sleep which results is followed for a few hours by an almost normal condition until the recurrence of excitement. This residuum is frequently associated with others, such as one of the respiratory residua, as in Morley Fletcher's case.¹¹¹

4. *Respiratory Residua*.—Respiratory disorders are concerned with the nervous mechanism of the act, not with the respiratory organs themselves. They may be present in the early stages also. Polypnoea has been frequently noted. In some cases this leads, as in physiological experiments on deep breathing, to tetany. Barker and Sprunt¹¹⁴ recorded such cases, and it occurred in my case seen in 1903 (vide supra). Cameron¹¹⁵ showed a tracing of this type which was obtained from a child with nocturnal excitement under his care. The periods of polypnoea were followed by prolonged apnoea in which the child became somewhat cyanosed. Marie, Binet, and Lévy¹¹⁶ have classified these respiratory residua into (a) changes in rhythm, polypnoea, bradypnoea, apnoea, periodic breathing, (b) spasmodic cough; (c) respiratory tics and abnormal rhino-laryngological sensations. The spasmodic cough may be of great violence and persistence. It, also, may be worse at night, as in a case recently under my care, associated with great increase in weight.

5. *Residual palsies* may occur, but they are much fewer and less marked than was originally anticipated would be the case. Their comparative rarity is in striking contrast to the results of poliomyelitis.

6. *Excito-motor Residua*.—The variety which this form of residuum can take is remarkable. Some of them are frequently associated with the Parkinsonian syndrome, and indeed are by some included in that.

Mlle. Gabrielle Lévy¹¹⁶ has recently published a monograph dealing with these phenomena very fully. They may take the form of choreatic, bradykinetic, myoclonic, or shaking movements. The term bradykinesia is used by Lévy in this connexion to indicate "large, slow, rhythmic global movements involving one or more limbs or the head and trunk." This definition has no relation to the use of the term by others to indicate the slowness of muscular action in Parkinsonians.

In most of these movements, which are involuntary and uncontrollable, rhythmicity is the characteristic. Sometimes the rhythm bears relation to the respiratory rate. Cruchet¹¹⁷ speaks of myorhythmia. Other movements which have been described include curious oscillatory movements of the lips in a lateral direction something like the movements of a rabbit's mouth. Cockayne⁶⁸ recently showed an example of this at the Royal Society of Medicine.

Another phenomenon, repeatedly seen, is a temporary inability to raise the eyelids. This may last for a few moments. There is no sign of any spasm of the orbiculares oculorum. In one of my cases, a boy with some Parkinsonian residua and a distinct perversion of moral character, this temporary blinking occurred when cycling with disastrous results to the machine. Automatic actions of various kinds have been described. Spasmodic tics, especially about the facial and masticatory regions, are not uncommon.

7. *Trophic Residua*.—Many cases of marked obesity following encephalitis have been recorded. In Barkman's¹¹⁸ case the man put on 42 kilos in weight in two years. This was accompanied by excessive sweating, loss of sexual power, and a feminine appearance. Bertolani's¹¹⁹ patient, a young woman of 23, gained 17.5 kilos in 15 months. Stiefler¹²⁰ saw a girl of 13 who gained 21.3 kilos in four months. One of Livet's¹²¹ patients, also a young woman, gained 13 kilos in 12 months. The interest of these trophic residua lies in their possible relation to hypophysis disorder, and the occurrence of polyuria, and also lethargy. In one of the post-encephalitic cases reported from the asylums a considerable growth of hair occurred on the back whilst she was an inmate, disappearing as the mental condition subsided.

(b) *Parkinsonism*.

This term, which originated in the French school, will be used here to signify those post-encephalitic residua which present features which are found in presenile paralysis agitans. As a matter of fact, many of these cases of Parkinsonism have as their chief signs the immobile facies, to which Parkinson, in his original essay in 1817, made no reference, and plastic rigidity, to which his allusion is very slight and incomplete. In spite of this, the term is convenient, and it is desirable, at present, to keep the post-encephalitic and the ordinary presenile forms distinct from each other for descriptive purposes until more is known of their relations to one another.

Before the present appearance of epidemic encephalitis cases of paralysis agitans below 40 years of age were very uncommon. Willige,¹²² in 1911, was able to collect only about 20 such cases from the literature up to that date. Of these, the earliest age of onset was 18 to 20 years. At the present moment there are, probably, more than that number of complete cases, as a result of encephalitis, in children under 15, in this country. On the continent the numbers are probably even greater. Goldflam¹²³ speaks of "an epidemic of paralysis agitans" in Warsaw. It is estimated that 25 per cent. of the cases suffer from this residuum. It may occur in two forms, "early" and "late Parkinsonism."

Early Parkinsonism.—The "early" form may appear within a few days of the onset of symptoms. In one of my first series of cases,¹²⁴ a woman, aged 56, "the facial expression was so suggestive of 'Parkinson's mask' that I thought at first she must have paralysis agitans." This was within a week or two of onset of symptoms. Buzzard,¹²⁵ however, was the first to describe a complete picture of early Parkinsonism in a man who began with encephalitis ten days previously. Kinnier Wilson¹²⁶ also recorded a case beginning in the 1918 outbreak. In more recent outbreaks the number of these early cases has been very large.

"Late" Parkinsonism.—The "late" form may occur only after a long interval. Souques,¹²⁷ Girardi,¹²⁸ Rathery and Cambessédès¹²⁹ described cases in which the interval was 9 to 12 months. Guillaïn and Gardin,¹³⁰ Sicard,¹³⁵ and Souques,¹³⁶ 15 months; Parkes Weber,¹³¹ Renaud,¹³² and Bing,¹³³ 18 months; McAlpine,⁶⁸ 3½ years. This interval may be free from symptoms of any kind (De Lisi¹³⁴). In a few cases the evidence of this is striking. In Renaud's case¹³² the man was on military duty for several months after recovery from encephalitis. In Guillaïn and Gardin's¹³⁰ case the patient during the interval served as mechanic on an American liner and whilst in America worked as cowboy, labourer, and post-office official. Meyer¹³⁷ records the case of a woman who had encephalitis, recovered, became pregnant a year later, and Parkinsonian at the sixth month of pregnancy. Lévy¹¹⁶ reports a similar series of events two years after encephalitis. Parkes Weber¹³¹ was the first to call attention to late Parkinsonism following an ambulatory attack. On the other hand the interval, even if long, may be not one of apparent recovery, but some one or more of the other residua are present, upon which Parkinsonism is grafted. Probably this is the more common course.

CLINICAL DIFFERENCES BETWEEN PARKINSONISM AND THE PRESENILE FORM OF PARALYSIS AGITANS.

These may be classified under three headings: (1) Parkinsonism is often something less than paralysis agitans; (2) it is often something more than paralysis agitans; (3) it differs in its mode of onset and its manner of progress.

1. The feature which is usually absent or minimal is the typical pill-rolling fine tremor. Although present in a few cases, it is exceptional. Even where the general affection involves the whole trunk and limbs, the tremor may not be present in this form.

Another most common feature is the limitation of parts affected. Amongst my cases at the present, one boy has an immobile facies and head, otherwise nothing, below the neck he is a normal active person; one woman has immobile facies and rigid right arm; another has immobile facies, rigid left arm; a man has complete rigidity of the face and all the limbs with extreme slowness of action; another man has immobile facies and festination, but his hands are hardly affected; he can take a watch to pieces, clean it, and put it together again. Whilst in paralysis agitans it is not unusual for one limb or one side to be affected at first, yet as a rule it extends fairly soon. In these cases as the years go on such extension does not seem to be occurring.

2. The frequency of other residua in association with Parkinsonism is common. Such residua may be of any of the above described forms. In fact, the combinations are at times bewildering. In one of my cases, a girl, five years after the attack, there are now present: mask-face, muscular jerks, recurring attacks of lethargy, spasmodic fixations of the jaw, unequal pupils, nystagmus, loss of convergence, nocturnal restlessness and excitement, left foot-drop—with inversion. With regard to this curious last-named feature Collier¹³⁸ has shown a very similar case in a woman of this type in whom foot-drop was also present.

3. As regards onset and progress, it is obvious from what has already been said that this is very different from what is familiar in presenile paralysis agitans. The mask-face is, as a rule, of somewhat slow and later development in paralysis agitans. In Parkinsonism it is early and often almost sudden in appearance. As to course and progress, it is yet too early to know how these cases of Parkinsonism will eventuate; but at least some of them in this country have shown no tendency to get worse whilst under observation for four or five years, and a few have shown distinct if slight improvement.

Bing and Staehelin,¹³⁹ out of 73 cases, saw Parkinsonism chiefly in the lethargic forms, and none in those cases in which excito-motor phenomena predominated.

MORBID ANATOMY OF RESIDUA.

The question as to the site and nature of the processes which give rise to the various later manifestations is one which is at present receiving widespread attention on all sides. Whilst much of this is still unsettled, and even in certain respects controversial, certain facts have come to light which are of considerable interest.

In 1919 Buzzard and Greenfield²⁷ in this country described "calcareous degeneration of the vessel walls and clots" in the brain of a fatal case. In the basal ganglia there were "very many calcareous deposits in the walls or lumen of larger thrombosed vessels," "depositions of lime salts in perivascular bleedings," &c. In one specimen the vessel walls were so thick and calcareous as to cause trouble in cutting sections. Buzzard at that time suggested that the late clinical complications might be due to secondary vascular disturbances. In 1921 Dürck¹³⁹ examined the brains of 15 fatal cases of epidemic encephalitis. He found marked calcification in 12 of them. The ages of the patients ranged from 20 to 60 years; duration of disease, eight days to five weeks. There was no ordinary athero-sclerosis of the cerebral vessels in any of them. The deposits of calcium were found in three forms: (a) less commonly, as incrustations around ganglion cells; (b) as free flakes in the tissue substance; and (c) as deposits in the vessel walls. The two latter were very much the commoner. These changes were well marked in a case which had only lived for eight days. This early appearance may explain the occurrence of early Parkinsonism. It is comparable, in rapidity of occurrence, to the similar calcium deposits which Herzog¹⁴⁰ found in the tunica media of the small and middle-sized vessels of the brain within 4 to 11 days after poisoning by coal-gas. A similar early calcifica-

tion is found in the renal tubules after poisoning by mercurial salts.

Another point which Dürck calls attention to is the sharp limitation of calcium deposition to certain circumscribed areas. These do not correspond with the areas of highest toxi-infectious damage. There may, or may not, be preceding hyaline changes in the vessel wall. The calcification is found chiefly in the media and inner part of the adventitia. The intima is only involved later if at all. These findings have been confirmed by others. Schminke,¹⁴¹ in two cases of encephalitis in children, attributed nodules of softening to calcification of vessels. Symonds²⁸ saw marked hyaline changes in Parkinsonism with some calcification in the corpus striatum. Greenfield (personal communication) has recently found extensive calcification in parts of the globus pallidus in a similar case. He also notes the limitation of these changes to circumscribed areas.

It is thus evident that the original observation of Buzzard and Greenfield, in 1919, that acute calcification of the cerebral vessels is produced by epidemic encephalitis has been amply confirmed, and that, as Buzzard suggested, the residual troubles may be due to interference with the circulation. As yet the exact site or sites, interference with which leads to Parkinsonism in the one case and paralysis agitans in the other, has not been agreed upon. The work of Kinnier Wilson on progressive lenticular degeneration, O. and C. Vogt and Ramsay Hunt on paralysis agitans points to changes in the corpus striatum. Trétiakoff, Souques, and Lhermitte, however, find constant changes in the substantia nigra in that disease. Whether either or both these sites are necessarily involved remains to be settled.

RELATION TO CHOREA.

The similarity of some encephalitic cases to Sydenham's chorea gravis has been already referred to. The connexion between the two may lie in the site affected and the nature of the lesion. Greenfield and Wolfsohn^{106b} recently reported upon the microscopic changes in the brain from a case of acute chorea under R. Hutchison. The child died ten days after onset. Vegetations were present on the endocardium. They found the chief lesions in the head of the left caudate nucleus, but the whole of the basal ganglia, cortex, and centrum ovale were affected to some extent. The congestion of the vessels, the emergence of small round cells from the walls of the capillaries, and the diffuse neuronophagy resembled very closely the picture of encephalitis lethargica in the earlier stages, which Greenfield²⁷ has described.

CONCLUSION.

Considering its comparatively light incidence upon the population this disease has caused a large amount of death and suffering. As yet no means of preventing or checking it is known. It is to be hoped that some increased knowledge of many obscure nervous disorders may arise from the many stimuli to their investigation which it has provided.

In conclusion, I desire to express my grateful thanks to each and all of many friends who have given valued assistance in preparing these lectures, particularly to the Ministry of Health for much help, and, not least, for the invaluable bibliography contained in its recent report.

THE IMPORTANCE OF PROTEIN HYPERSENSITIVITY

IN THE DIAGNOSIS AND TREATMENT OF A SPECIAL
GROUP OF EPILEPTICS.

By R. L. MACKENZIE WALLIS, M.D. CAMB.,

CHEMICAL PATHOLOGIST, ST. BARTHOLOMEW'S HOSPITAL, LONDON;
LECTURER IN CHEMICAL PATHOLOGY TO ST. BARTHOLOMEW'S
HOSPITAL MEDICAL COLLEGE;

AND

W. D. NICOL, M.R.C.S., L.R.C.P.,

ASSISTANT MEDICAL OFFICER, LONDON COUNTY MENTAL SERVICE,
HANWELL MENTAL HOSPITAL.

In Collaboration with

Sir MAURICE CRAIG, M.D., F.R.C.P. Lond.

THE possibility of food poisons or food susceptibility as a factor in the aetiology of certain forms of epilepsy has been advocated for many years. The basic idea is, therefore, by no means new, and we do not wish to claim any originality. The subject of protein hypersensitivity and its relation to asthma, urticaria, migraine, &c., has engaged the attention of one of us (R. L. M. W.) for several years. The application of such tests to cases recognised as a special type of epilepsy was suggested by Sir Maurice Craig over two years ago. The clinical aspects of such a group were recorded by him, and he has kept in touch with all the cases investigated. The whole subject teems with interest and offers a wide field for further research along certain definite lines. We submit the results of these investigations with due regard to our inability to interpret them in the light of our present knowledge, which inability we regard as inevitable, although it is a matter for regret. The research is being continued,¹ and this paper, therefore, is in the nature of a preliminary communication.

Protein Hypersensitivity Tests.

All the tests have been carried out with proteins prepared by R. L. M. W. under certain definite conditions. In many cases pure crystalline proteins have been isolated from various foodstuffs, and these have been grouped together. As a result we have five groups of proteins which are used for purposes of testing food protein sensitivity. These groups consist of:—

(1) Egg proteins: crystalline egg albumin of various types; (2) meat and fish proteins: from beef, mutton, veal, chicken, game, fish, shell-fish, &c.; (3) milk of various animals; (4) vegetable proteins: ground-nut, vegetables, fruits, nuts, legumes; (5) cereals, including all the common types of cereal proteins; (6) peptone; (7) control: a solution of decinormal sodium hydroxide.

These proteins, as far as possible, are kept in the solid form in a refrigerator and weighed out into sterile test-tubes before use. They are dissolved in freshly prepared decinormal soda, 20 mg. to 10 c.cm. of soda being the usual strength for the purposes of the tests. As the solutions deteriorate on standing, they are made up fresh every day, especially in the summer months, and, as far as possible, all the patients are tested on the same day. The tests are done on the forearm by first cleansing the flexor surface with alcohol or ether and applying a small drop of the testing solution. The skin surface is just broken by gentle scratching with a blunt-pointed scalpel or needle, care being taken to avoid any bleeding. The six or seven tests are applied to the skin, and a control with decinormal sodium hydroxide is also carried out. A positive reaction appears obvious almost immediately after the scratching has been completed, since in 15 seconds an area of hyperæmia appears, which spreads outwards and usually extends over an area the size of half-a-crown.

¹ The research was extended subsequently to Hanwell Mental Hospital, where the patients were under controlled conditions.

After leaving the protein solutions in contact with the broken skin for 10 minutes they are washed off and the results of the skin test noted. In cases where a positive reaction has occurred a small but definite wheal appears, which still retains its hyperæmic area around it. The negative tests and controls often disappear so rapidly that it is difficult to see where they have been applied. To make certain of the positive reaction we usually apply a clean glass microscope slide to each test and note whether the hyperæmic area can be blanched by pressure alone. In true positive reactions this does not occur.

The question of the best time to do the tests is of the greatest importance. Our observations tend to show that the tests succeed best when the patient is not fatigued. It was found that the sensitivity of patients to proteins varies considerably, according to the time when they are carried out. It so happened that two epileptics were tested immediately before a fit, and in both cases they reacted strongly to proteins (one to the five groups of proteins, the other to three groups). After the fits the sensitivity to a particular protein may disappear, but the time that elapses before the patient becomes desensitised varies. An epileptic has been found to be negative to all proteins within 3½ hours after a fit, while in others the time is considerably longer. In those patients who have fits over a period of some days we have found that at the commencement of the attack they remain sensitive, but at the end of the attack they no longer react. The best time, therefore, is just before an attack (though immediately before an attack a patient may be hypersensitive and may react to all proteins) or as long an interval as possible after the previous one.

Treatment.

Treatment comes under two headings. In private practice the ideal method can be applied, which consists in removing the offending protein or proteins from the patient's dietary, and, if necessary, in desensitising the patient by the administration of protein vaccines in small and graduated doses. In a mental hospital, where patients are segregated together, it is often found difficult to eliminate the particular food, though it is hoped that this may be tried in certain cases. Peptone² given by the mouth is of value to patients sensitive to that particular peptone. Cereal vaccines are being given to the patients at Hanwell, who have been found to be sensitive to cereals, but it is too early to report any definite results at present.

Summary of Results.

The tests for protein hypersensitivity have been carried out on sane patients in private practice and on patients in a mental hospital suffering from epilepsy with insanity. The patients in private practice were selected from clinical experience as a general rule. They appear to be quite healthy persons, usually inclined to obesity, and not excitable or markedly unstable. This grouping of the symptoms was described by Sir Maurice Craig as characteristic of the particular type discussed in this paper. It enabled him to select the right type of case for investigation, as shown by the frequency of positive results to the protein skin tests in his cases. This class does not respond to bromides; this observation alone may suggest the group to which the patient belongs. Again, many patients complain of digestive disturbances and are brought by anxious relatives for an opinion as to the diet the patient should be given. The patients at Hanwell suffering from epilepsy with insanity were not selected. All epileptics, except the very old and those with congenital imbecility, were examined. Tests were carried out on 122 epileptics

² This peptone is given in the form of gelatin capsules, each containing 1 gr. of peptone. One gr. twice a day after food has been found sufficient for this purpose. It is most important to give it after food, not before. Further, some cases react very strongly, so that the dose has to be diminished or suspended for some days. The best preparation we have found is that known as medicinal peptone.

(68 females and 54 males). Of these, 46 (28 females, 18 males) gave positive reactions to different proteins, while 76 (40 females and 36 males) did not react at all. These results are in accordance with our contention that only a certain type of epileptic shows protein hypersensitivity. Only a very few in this series corresponded clinically to the type described by Sir Maurice Craig. In this series of epileptics tested at Hanwell it was found that 28 patients reacted to peptone, 15 to cereals, 15 to fish and meat, 9 to vegetables, 9 to eggs, and 3 to milk. A large number of non-epileptics react to protein hypersensitivity also, and this has been observed in patients suffering from asthma, urticaria, migraine, &c. At Hanwell control tests were performed on 100 persons, of whom 13 were staff, and 70 were cases of dementia præcox, the remainder consisting of other types of insanity. All the tests proved negative, with the exception of four cases of dementia præcox, who reacted slightly to peptone.

The result of these observations has shown conclusively that in some cases where it has been possible to adjust the diet on the basis of skin tests, no further treatment has been necessary. The work carried out at Hanwell has emphasised the difficulties of the dietetic treatment, and made necessary the production of a reliable substitute, but so far we have not been able to fix the dosage suitable for each individual case.

Peptone was given orally to 24 patients. In some cases the fits have become less frequent, and, in a small proportion of cases, there has been some mental improvement as well. In two cases the peptone made them decidedly worse—i.e., they became confused and "lost"; after the treatment by peptone it was found that some patients were no longer sensitive to that particular peptone. We found that some patients reacted more favourably to peptone when the dose was reduced from 2 gr. twice a day to 2 gr. once a day. The control of the fits and the associated mental condition does depend to a large extent on the dosage of peptone given, and in this respect resembles bromide treatment. It is possible that, with smaller doses, the patients may be controlled just in the same way as with bromides in certain types of epilepsy. With regard to the length of time the treatment should continue, we are at present unable to give a satisfactory answer. Again, we cannot say when a patient exhibiting an idiosyncrasy to one or more foods can with safety resume a normal diet.

The tests serve as a guide not only to diagnosis, but also to treatment. Those patients who have shown signs of improvement with peptone are usually those who have recently been admitted to the Mental Hospital. This can possibly be explained by the fact that the central nervous system is not damaged to the same extent as in a patient with a prolonged history of epilepsy. The difference in the results obtained in private practice, as compared with those in asylum practice, is no doubt due to difficulty of controlling the diet in the latter and the actual deterioration caused to the central nervous system through constant seizures.

This is one reason for urging the importance of early diagnosis of this type of epilepsy in the hope of preventing further attacks. That there is foundation for this would appear to be well illustrated by the cases which we have cited. It seems to us that by the application of the protein skin tests we have valuable confirmatory evidence of the possibility of a case of epilepsy falling into this group. The more our knowledge is extended, and the more we can group accurately, so much the better for treatment. Our special group is clearly one which has attracted attention throughout the ages. Since this type of epilepsy begins in early life, the secret of success is early diagnosis. In asylum practice this is impossible, and so vitiates good results. The diagnosis and treatment by means of skin tests, peptone, and diet applies only to one special type, and we do not wish to convey the impression that we have a panacea for all types of epilepsy. As to the mode of action of the

proteins, certain explanations offer themselves to us, but we consider them far too speculative with our present knowledge. The condition known as migraine, and its association with food poisons and food idiosyncrasy, is of particular interest in this connexion, and its ready response to dietetic treatment has been observed by us. The production of epileptic seizures in one group and attacks of migraine are so closely allied as to suggest a common pathological change in the two conditions.

Illustrative Cases.

The following are illustrative cases:—

CASE 1.—Male, aged 37, under care of Sir Maurice Craig. Fits began at 29; has had 14 fits in eight years. When first seen and tested, June 17th, 1921, was found to be sensitive to egg proteins. This reaction was very definite and coincided exactly with the history, and with the patient's natural dislike of eggs. A survey of the 14 fits, and their time of occurrence, gave clear evidence of the close connexion with eggs in the diet. On restriction of diet by exclusion of eggs in all forms only two fits occurred, and these were traced to the patient taking custard by accident. For nearly a year this patient has been quite free from fits, has had no bromides or sedatives of any kind, and has been able to carry on his work without interruption and no signs of impending fits.

CASE 2.—Male, aged 16½ years, under care of Sir Maurice Craig. Fits commenced at 12 years; he has suffered from repeated seizures ever since. Three weeks before being tested had a fit. The tests showed a definite sensitivity to milk protein. The attack three weeks previously followed on a long walk at the end of which he felt thirsty and consumed two glasses of milk at a dairy on his way home; the fit began just one hour after he had consumed the fresh milk. The patient was not aware of any idiosyncrasy to milk, but on a diet free from milk has had no further attacks, and is still under treatment.

CASE 3.—Female, aged 15. Tested on June 10th, 1922, she reacted to vegetables, fruits, and cereals. On a diet free from these she has only had one fit since, and this occurred after she had been given salad by mistake.

CASE 4.—Female, aged 21. Has suffered from fits for some years. In association with the fits she has urticaria. Appears quite healthy and is inclined to obesity. Tests showed a well-marked reaction to cereals, and also to peptone. Since commencement of treatment by diet and peptone has had two attacks of grand mal, traceable to errors in diet, occurring when she was over-fatigued. There were no epileptic equivalents after these two attacks, which were of short duration, and mental recovery was much more rapid than previously. Since August 30th has been quite free from attacks, and is now much better. Under bromide treatment for many years, without any influence over the fits. In addition she has taken luminal, 2 gr. nightly, for some time without effect in reducing either the number or severity of the attacks.

CASE 5.—Male, aged 5½, under care of Sir Maurice Craig. Suffered from petit mal for three years, uncontrolled by bromides. Was found to be sensitive to eggs, and also to vegetables. These articles of food were found to be the chief constituents of his diet; on their removal fits became less, and finally disappeared. There have been no attacks for nearly a year, and the improvement in the boy's condition, both physical and mental, is very well marked. With the exception of a slight tendency to excitability, he appears to be a normal healthy boy.

CASE 6.—Male, aged 14, under care of Sir Maurice Craig. His first seizure, 15 months previously to being seen, was severe and accompanied by signs and symptoms which led to the diagnosis of ptomaine poisoning. Skin tests showed him to be sensitive to vegetables and fruits; his diet was adjusted accordingly, and he remained free from fits for nearly six months. A severe seizure followed the eating of mushrooms; during this attack, the patient was re-tested, with negative results. Examinations of the blood, urine, and stools gave no evidence of pancreatic or hepatic insufficiency. The patient is still under treatment, and so far has had only one attack, of short duration.

CASE 7.—Female, aged 5½, under care of Sir Maurice Craig. Had attacks of petit mal with great regularity since 1½ years of age. The tests showed a very definite sensitivity to cereal proteins. The mother, who proved an admirable witness, stated that whenever she gave the child oatmeal her stomach became enormously distended and a seizure followed. Removal of all cereals from diet followed by complete disappearance of distension and petit mal; this condition is maintained after 18 months without any further treatment, and more particularly exclusion of bromides.

Illustrative Cases of Patients Treated with Peptone.

CASE 8.—Female, aged 39; tests showed definite sensitivity to peptone and cereals. Peptone was given, 2 gr. b.d., from June 6th, 1922. At first the patient became very lost, confused, and spiteful; since August she has improved both mentally and physically, and has put on 6 lb. in weight. She is neither lost nor spiteful now, and is working. Fits are less frequent. Does not now react to peptone.

CASE 9.—Female, aged 27; showed sensitivity to peptone and, very markedly, to cereals. Two gr. peptone b.d. from June 6th, 1922. Worse on treatment at first; she became very confused, troublesome, and depressed. Is now much brighter mentally, but continues to have fairly frequent attacks of petit mal, though by no means so many as she had previously.

CASE 10.—Female, aged 33; tests showed sensitivity to fish and meat and peptone. Peptone 2 gr. b.d. from June 6th, 1922. Patient subject to frequent screaming attacks; during first fortnight of treatment she became extremely abusive, and mistook identities, but she was free from screaming attacks. In August she was very much better, but the screaming attacks returned, though not so frequent. The fits are less frequent, and mentally she is much clearer than she used to be. When tested last, on Oct. 22nd, she failed to react to peptone, but still reacted to fish and meat.

CASE 11.—Male, aged 27; tests showed a sensitivity to peptone, given orally 2 gr. b.d. from June 6th, 1922. Mentally he remains the same, but his fits are fewer. He used to have fits in batches, but since treatment has not had a batch.

CASE 12.—Male, aged 37; tests showed a sensitivity to peptone and cereals. Peptone 2 gr. from June 6th, 1922. At first the fits became more frequent, but now they are less. He is not so irritable, and there is little confusion after fits. Mentally he has improved.

CASE 13.—Male, aged 19; tests showed sensitivity to peptone and cereals. Peptone given from Sept. 14th, 1922. From being in a state of gross confusion he was able to get up, and was working within a week of the treatment being started. His fits are less frequent, but recently he has had a relapse, and died in status epilepticus.

We would express our indebtedness to Sir Maurice Craig for the help and advice he has so willingly given us, and also for his encouragement and interest. In allowing us to carry out the investigations at Hanwell, we would offer our grateful thanks to the committee of the Hanwell Mental Hospital, and to the medical superintendent, Dr. A. W. Daniel. To the nursing staff of the hospital we owe our indebtedness for the careful records they have kept of the patients under treatment, and for their hearty coöperation.

SOME CONGENITAL ANOMALIES OF THE EYE

AND THEIR CONFUSION WITH ACQUIRED CONDITIONS.¹

By IDA C. MANN, M.B., B.S. LOND., D.O.M.S.,

OPHTHALMIC SURGEON TO THE ELIZABETH GARRETT
ANDERSON HOSPITAL.

THE eye, in common with the rest of the body, is not exempt from the liability to occasional imperfect or aberrant development, with this difference, however, that whereas congenital malformations in other parts, such, for instance, as hare-lip, spina bifida, or imperforate anus, are usually self-evident as errors of development and easily diagnosable, the lesser abnormalities of the eye may sometimes closely simulate pathological states. Failure to recognise their congenital origin may thus lead to misapprehension and in some cases to much unnecessary anxiety on the part of the practitioner. This apparent difference is no doubt partly due to the ease and minuteness with which the eye can be examined, so that less degrees of departure from the normal will be recognised in the eye than is possible in other parts, and partly to the fact that, the defects being in many cases invisible without an ophthalmoscope, they

escape the notice of the patient or his relatives until discovered by examination.

Naturally, as in other parts, there are also gross errors of development of the eye which are immediately evident at birth (such as microphthalmia, cryptophthalmia, and cyclopia). These do not require description here, since they are obviously developmental and are unlikely to be confused with anything else or to demand treatment. It is the smaller anomalies, in themselves of no clinical value, which may easily be confused with pathological conditions of grave import.

Differential Diagnosis of Congenital Abnormalities from Affections of the Fundus Oculi.

Affections of the fundus will be dealt with first, since they present by far the most difficult diagnostic problems.

From Papilloedema.

A young patient may come to his doctor complaining of increasing headache, irritability, and inability to concentrate on work. In the course of the examination, which reveals no definite physical signs, the eyes are inspected. There is no external abnormality and the patient states that his vision has been good, but that lately he has noticed occasional mistiness. On ophthalmoscopic examination it is seen that the edges of the optic disc are blurred and that it is distinctly redder than normal. The question at once arises as to whether this is a case of early papilloedema from cerebral tumour, and this diagnosis may easily be made if one forgets the existence of the congenital condition known as pseudo-neuritis.

Pseudo-neuritis is generally associated with hypermetropia, sometimes of high degree (6 D. or more), but not necessarily. This hypermetropia will give rise to severe headache, blurring of vision on close work, lassitude, and the whole train of symptoms of asthenopia, which, when taken in conjunction with an apparent early papilloedema, may easily simulate signs of raised intracranial pressure. The differential diagnosis rests on the following facts. Pseudo-neuritis is almost invariably associated with hypermetropia. The swelling of the disc is more apparent than real. There are no hæmorrhages and no exudate. The appearance is absolutely stationary and the symptoms can be completely relieved by correcting the hypermetropia. A cerebral tumour sufficiently advanced to cause papilloedema will almost certainly have given rise to vomiting as well as headache, but a swelling of two dioptries or more is certainly pathological and pseudo-neuritis should not be diagnosed.

One should bear in mind in considering the diagnosis of papilloedema the fact that apparent blurring of the upper and lower edges of the disc is often seen in high degrees of astigmatism and is merely an optical effect caused by the impossibility of focusing all parts of the disc distinctly at the same time. As regards the colour of the disc, it should be remembered that it is very variable, normal degrees of vascularity shading imperceptibly into states of definite hyperæmia. Generally dark-complexioned people have discs of richer colour than blondes. The very variable pigment ring round the disc should not be mistaken for a pathological condition.

From Glaucoma.

Another and rarer condition of the disc may cause anxiety by confusion with the cup seen in chronic glaucoma. In the true glaucomatous cup the vessels can be faintly seen emerging from the centre of the disc at the bottom of the cup and curling over the overhanging edge, while the field of vision shows contraction, especially on the nasal side, though central vision may be of normal acuity. In the congenital condition which resembles this all the vessels emerge round the edge of the disc and no central vessels can be seen. Sometimes the surface of the disc is level and sometimes deeply depressed below the surface of the retina (coloboma of the disc),

¹ An address read at the meeting of the London Association of the Federation of Medical Women held on April 10th.

in which case the appearance much resembles a glaucoma cup, but is often much deeper and more irregular, and may show pigmentary deposits. It is interesting to note that a cupped disc with vessels emerging round the periphery is normal among most of the Carnivora. The visual acuity in these congenital cases may be normal or diminished. In one case seen by me there was also a coloboma of the choroid below the disc, which gave rise to a marked defect in the upper part of the field of vision. The typical appearance of this coloboma, however, made the congenital origin a matter of certainty.

An abnormally deep physiological cup will not be confused with a glaucoma cup if it be remembered that in glaucoma the margin of the cup is at the margin of the disc (though the disc may be surrounded by a white ring of exposed sclera), while in a deep physiological cup there is always a rim of normal disc round the periphery.

From Glioma Retinae.

One is often confronted with infants brought because the mother fancies there is something wrong with the child's eyes. She may even have noticed a peculiar sheen in the pupil. Other conditions besides glioma of the retina should then be borne in mind. The congenital conditions most likely to cause doubt are the various degrees of persistent hyaloid artery. In well-marked cases a vessel stretches through the vitreous from the optic disc to the posterior surface of the lens. Here it may appear only as a small central opacity in the pupil, or it may be associated with persistence of the posterior part of the vascular capsule of the lens, in which case the back of the lens will be seen covered with a more or less shining membrane in which blood-vessels can be seen. This appearance much resembles a mass of vascular new growth in the vitreous, but it must be remembered that in glioma retinae the tension in the posterior part of the eye is increased and the lens and iris pushed forwards, so that the anterior chamber is very shallow, while in persistent hyaloid artery the anterior chamber is normal or even deeper than normal.

In less marked cases the posterior part of the lens is unaffected and only the proximal part of the artery persists. It may be seen as a cord-like structure stretching forward from the disc, sometimes containing blood and sometimes veiled with a film of connective tissue, which may also extend over the branches of the *Arteria centralis retinae* on the disc. This appearance may resemble a new growth, but it lacks the golden and clear-cut appearance of early glioma and there are no satellite growths scattered over the retina. It is a point of anatomical interest that the hyaloid artery normally breaks up into several branches in the vitreous before reaching the lens. In two human embryos which I have examined there were five branches spreading out in a fan from the main trunk. If more than one of these branches persists the condition may be mistaken for *retinitis proliferans*.

From Retinitis and Choroiditis.

The diagnosis and prognosis of general conditions, particularly those associated with arterio-sclerosis, albuminuria, or syphilis, are often materially assisted by an examination of the *fundus oculi*. In such cases the physician is particularly on the look-out for hæmorrhages, white patches of exudate, pigmentary disturbances, and areas of choroidal atrophy. Here, again, congenital defect sets a snare for the unwary. In the first place, the presence of *opaque nerve fibres* either at the edges of the disc or in patches along the course of the larger vessels may be extremely misleading. Unless excessive they cause no symptoms, so no help can be derived from the history. In appearance they are feathery white finely-striated patches of varying size, always with a fringed appearance at their peripheral edges. There is no disturbance of the retina apart from them and the vessels are

usually normal, though, of course, arterio-sclerosis may coexist. They are very likely to be mistaken for patches of exudate, though these latter are always more creamy in tint, soft and fluffy in texture, and show no peripheral striation. They may frequently be seen to involve the deeper layers of the retina, whereas opaque nerve fibres are superficial. Exudate is almost always associated with hæmorrhages and changes in the vessels and is often accompanied by a "macular fan," while it is rare for opaque nerve fibres to involve the macula, and if they do so it is in the form of a dense white patch and not a fan-shaped figure.

Hæmorrhages from the retinal vessels are usually quite straightforward, but there is a curious and rare condition which may be confused with them. This anatomical peculiarity is known as a choroido-vaginal vein (or posterior vortex vein). Such a vessel is a very large choroidal vein which collects blood from a variable area of the choroid and leaves the eye in the neighbourhood of the optic disc. It is very broad (sometimes as much as half the diameter of the disc) and lies on a deeper plane than the retinal vessels. Like the smaller choroidal vessels which are sometimes visible it has no light streak, but is flat, lustreless, and ribbon-like. Its large size, deep red colour, and lack of reflex make it look very like a patch of extravasated blood, but if it be examined carefully it will be seen to be a large vessel, and pressure on the eyeball will cause it to empty and disappear. Such choroido-vaginal veins occur most often in myopes, though they have been seen in poorly pigmented emmetropic and hypermetropic eyes. They sometimes leave the eye through the floor of a myopic crescent.

Patches of *choroiditis* are often of great diagnostic importance. They appear, unless seen early in the active stage, as glistening white areas surrounded by irregular heapings of black pigment. The retinal vessels often pass over them, but choroidal vessels are absent. The patches are usually multiple and vary in shape and size. Confusion may arise between patches of atrophy from choroiditis and one or other of the forms of *congenital coloboma of the choroid*. In coloboma the chorio-capillaris is absent over a portion of the fundus. Both choroidal and retinal vessels may be seen coursing over the white floor of the coloboma. They are usually small. The coloboma may be ectatic; patches of choroiditis, except in high myopia, are level or nearly so. Scattered pigment may be present or there may be a thin line of pigment at the edge of the coloboma, but there is not the exuberant heaping up of pigment seen in choroiditis. In coloboma there is only one patch and it is most often situated below the disc, with its greatest diameter in the vertical. Its anterior edge is frequently not seen, though it may reach to the edge of the pupil, constituting a coloboma of the iris.

Colobomata may occur in atypical situations and hence be misleading. The most important of these is the macular coloboma, which is rare and somewhat of an embryological puzzle. It much resembles a single patch of central choroiditis. It is usually horizontally oval, the edges are sharp, it is often surrounded by a yellowish zone, and it may be pigmented. There may be a history of defective vision from birth but not necessarily, and it may occasionally be extremely hard to diagnose. The chief features are that it is absolutely stationary and it is the only patch seen. The so-called Fuchs's coloboma is a white crescentic area below the disc and is due to an anomaly of development of the upper end of the choroidal fissure. It is usually found in hypermetropic eyes and is not likely to be mistaken for anything else unless its white colour and the patient's poor visual acuity (from the refractive error) lead to a suspicion of atrophy.

Pigmentary Disturbances.—These occur with frequency in choroiditis, retinitis, and high myopia. Congenital anomalies of pigmentation may be either in the direction of excess or deficiency. The variable

pigmentation at the edge of the disc has been referred to above. Pigment in this situation, even when in isolated masses, is seldom pathological unless accompanied by signs of exudate or choroidal atrophy. The amount of pigmentation seen over the retina varies with the complexion of the individual, from the almost chocolate colour of the negro's fundus to the bright red apparently pigment-free albinotic eye.

On the whole, then, the differential diagnosis of intraocular congenital anomalies rests on the observation of minute details of their structure and colour and to a certain extent on the appreciation of their stationary nature, though it is often undesirable to postpone an opinion until this last point has been verified.

Differential Diagnosis of Anomalies of Parts Anterior to the Vitreous.

Anomalies of the parts of the eye anterior to the vitreous are also apt to give rise to difficulty, though on the whole their congenital nature is more obvious, both because the history is of some value and the parts concerned are more easily examined.

From Iritis.

The chief signs of old iritic mischief which may lead to confusion with congenital conditions are the irregularity of the pupil, the presence of organised exudate and adhesions to the anterior capsule of the lens, and the alteration in colour of the affected eye as compared with the other in unilateral cases.

Irregularity of the Pupil.—In the first place, one must mention the condition of coloboma of the iris. Here the pupil is pear-shaped or oval with the narrower part usually below, though not always. The defect may be complete—i.e., a forward continuation of a coloboma of the choroid, or incomplete and not extending to the root of the iris, or there may be a narrow bridge of iris uniting the two margins of the cleft at one point. Here the possible occurrence of fundus abnormality, the absence of adhesion of the iris to the lens, and the dilatation of the pupil under atropine and, if one may use a paradox, the regular irregularity of its shape, will assist the diagnosis.

In other cases the congenital malformation of the iris may take the form of extra holes beside the pupil, which itself may be abnormal in shape (polycoria). There is most frequently one extra hole near the pupil, the slender bridge of iris separating it sometimes resembling a band of organised exudate subdividing a normal pupil. Here a drop of atropine will help matters. In polycoria the primary pupil dilates and the accessory one merely alters in shape passively since it possesses no sphincter. In iritis with a band-like adhesion both the parts of the pupil will dilate except where they are held by the adhesion. A single pupil may sometimes be seen much displaced, usually up and in (corectopia). Here the light reaction is normal.

True adhesions of the iris to the anterior capsule of the lens may occasionally be found in cases of polycoria and corectopia. More commonly, however, they are simulated by tags of persistent pupillary membrane. These may vary from fine filaments scarcely visible to fairly dense bands crossing the pupil and sometimes passing forward to the back of the cornea. Their true nature can always be recognised by observing that they are attached to the anterior surface of the iris a little way from the margin (the *circulus iridis minor*), whereas inflammatory synechiæ always come from the edge of the pupil. Occasionally these tags of persistent pupillary membrane disappear during childhood, but leave behind them a very regular arrangement of brown pigment dots on the front of the lens. These differ from the pigment spots left by broken-down inflammatory synechiæ in their regularity and small size.

Congenital *heterochromia iridis* is occasionally seen, either one iris being of a different colour from the

other or different parts of the same iris varying in tint. The absence of signs of inflammation and atrophy will be noted.

From Results of Trauma.

Some of the above conditions may also resemble the results of trauma. The converse of this was well shown in a case seen recently in which the iris presented the appearance of a small clean-cut oval hole to the nasal side of the pupil, whence the possibility of polycoria. Only the history and the presence of a minute white opacity in the cornea immediately opposite the hole served to show that it had been caused by a perforating wound many years before. Coloboma of the upper or lower lid may occur in the form of a small notch, usually to the inner side of the mid-line of the eye. The eyelashes are absent in the coloboma. These defects in the lower lid are frequently associated with defective development of the malar bone. Various other anomalies, such as dermoids, skin bridges from the lids to the globe, coloboma of the iris, corneal opacities, &c., are often associated with congenital clefts of the lids.

The presence of corneal opacities must not be taken as absolute evidence of past inflammation or trauma since they may be congenital. The question as to whether they are truly developmental or are due to intra-uterine inflammation or trauma is debatable.

Coloboma of the lens may or may not be associated with coloboma of the iris. If it is not and the patient happens to come up with a history of injury, it is possible that the edge of the coloboma seen in the pupil may be mistaken for the edge of a dislocated normal lens: it is to be remarked, however, that the curve of the edge of a colobomatous lens is concave towards the pupil margin while that of a dislocated lens is convex. A congenitally dislocated lens may be very misleading in this connexion, though the history of poor vision from birth may help. Congenital dislocation of the lens appears to predispose to acute glaucoma.

From Disorders of the Motor Mechanism of the Eye.

In this group I have included those congenital conditions which simulate on the one hand acquired disease of the central nervous system, and on the other the common condition of concomitant squint.

Congenital ptosis may be unilateral or bilateral. It is often incomplete, the pupil being not quite covered. In slight cases the lids may show movements associated with those of mastication and deglutition (synkinesis), but no independent movement. In more marked cases there is defective upward movement of the eye. In all cases of congenital ptosis the pupil reactions and the accommodation are normal, and this fact is perhaps the most important in their diagnosis. Confusion may arise in cases seen apropos of other non-associated symptoms, where the history is vague. In these cases one has to think of the possibility of a syphilitic syndrome, or of myasthenia gravis, incipient bulbar palsy, cerebral tumour, or abscess. The fact that one eye only is affected does not in itself exclude early myasthenia gravis, as, in a case which I saw recently, a unilateral ptosis preceded the appearance of weakness in the tongue and lips and the other eye by several months. In this case the amount of ptosis was variable and there was rapid improvement under strychnine.

In practically every other condition which may be confused with congenital ptosis there is involvement of some or all of the other muscles supplied by the third nerve, and the pupil reactions are invariably affected. In cases of congenital ptosis which are hereditary there is usually marked limitation of movement of the globe and also sometimes nystagmus, but in all the cases so far reported pupil reactions and accommodation were normal.

Congenital defect of any one of the eye movements may occur alone, and in these cases the defect may be due to various anatomical causes, such as defective development of the muscle at fault, its abnormal

insertion or bifurcation, and absence or aplasia of the nerve. The resulting squint can be differentiated from a concomitant squint by the fact that the relation of the visual axes to each other is not the same in all positions of the eye, and from a true paralytic squint by the absence of secondary contracture and of diplopia, and, frequently, the presence of nystagmus.

Inequality of the pupils is often a valuable diagnostic sign, but it should be remembered that it may accompany marked dissimilarity in the refraction of the two eyes. In these cases it varies from time to time, and becomes less when the correcting glasses are worn.

Nystagmus dating from birth is associated with some defect of the eye which hinders the development of central fixation. Such defects should be carefully looked for in considering all cases of nystagmus. The commonest are opacities in the media (especially the lens and the cornea, either congenital or due to ophthalmia neonatorum), albinism, and occasionally complete colour blindness or aniridia. The presence of any of these will help to allay suspicions of disseminated sclerosis, cerebellar lesions, or Friedreich's ataxia. Congenital nystagmus is not accompanied by the sensation of movement of objects looked at and of vertigo, whereas acquired nystagmus frequently is.

From Melanotic Sarcoma.

There are two conditions which may give rise to grave suspicions of melanotic sarcoma if they are accidentally discovered during a routine examination. They cause no symptoms, but neither does an early sarcoma. The first of these is the presence of clusters of small deeply pigmented nodules at the edge of the iris. They are sometimes likened to bunches of grapes (*Traubenkörner*) and are of normal occurrence in horses. Their position and the fact that they do not appear to infiltrate the iris but rather hang from its edge may help to distinguish them.

The second condition consists of the presence of one or more small black dots in or just under the conjunctiva, often at the site of perforation of the anterior ciliary vessels. A faint dusky patch is often seen here in dark-complexioned people, but occasionally a definite black nodule is formed. These should always be carefully watched, since, though, like "moles" elsewhere, they may remain quiescent permanently, there is always just a possibility that they may enlarge, when they must be viewed with suspicion and submitted to treatment.

Other Congenital Conditions of Interest.

There are two conditions dating from birth which are interesting as they resemble senile changes, though they are of little diagnostic importance. The first is the presence of a white ring-like opacity in the cornea exactly resembling an *arcus senilis*. The second is congenital ectropion of the lower lid. This occasionally resembles the senile condition but may look like scarring. Ectropion of the lower lid is normal in St. Bernard dogs. The opposite condition—namely, entropion of the lids—is sometimes seen to occur congenitally. It is, of course, liable on superficial examination to be mistaken for trachoma, but the absence of granules or scars on the tarsal plate will distinguish it, even in the presence of pannus which may be caused by the rubbing of the lashes against the cornea.

Finally, there is a misleading condition of which I recently saw a good example. The patient, a woman, appeared to have a marked unilateral exophthalmos which suggested the presence of an orbital tumour. On examination, however, I found that the appearance of exophthalmos was solely due to the large size of the affected eye, which showed a refraction of -16 D., the other being practically emmetropic. The media in both eyes were quite clear and the corneae of the same size, there being no suggestion of buphthalmos. The patient stated that the condition dated from birth and that several other members of her family were similarly affected.

HEATING OF THE TISSUES OF THE BODY BY LIGHT AND HEAT RAYS.

BY LEONARD HILL, M.B. LOND., F.R.S.,

AND

J. ARGYLL CAMPBELL, M.D., D.Sc. EDIN.

(From the National Institute for Medical Research, Hampstead, London.)

RECENT experiments have revived interest in the question of the effects of the application of light, heat, and cold upon the temperature of the tissues of the body. MacLeod, Self, and Taylor,¹ and more recently MacLeod and Taylor,² determined the effect of the local application of heat and cold by means of electrically heated pads and glass tubes, heated or cooled with circulating water, upon the temperature of the unshaved and shaved skin of rabbits, and on the organs underlying the skin thus treated. They used thermo-electric couples mounted in hypodermic needles, and a galvanometer specially calibrated to determine the temperature of the tissue. They found that the changes produced varied with vascularity of the different tissues. Thus the temperature of the liver and the kidney was little affected by heating or cooling of the overlying skin, whilst that of the brain or of muscle was considerably altered. In no case was the general body temperature affected by such local application of heat and cold.

Sonne³ studied the effect of the various rays of the universal light bath (Finsen), and concluded that the luminous rays heated up a very essential portion of the aggregate blood volume of the organism to a temperature possibly exceeding the highest ever measured, without causing the body temperature to rise to any appreciable degree. He found that the luminous rays heated up the cutaneous blood 5.8° C. higher than do the infra-red rays. In the case of the luminous rays the subcutaneous temperature is above the skin temperature, whereas in the case of the dark infra-red rays the skin temperature is higher than the subcutaneous temperature. Sonne employed thermo-electric couples mounted in hypodermic needles, as did MacLeod and his co-workers.

In this paper we record results of experiments in which we exposed rabbits to the rays from the sun and from a carbon arc lamp, paying particular attention to the comparative effects on the temperature of the brain and of the body in general. We also record results of experiments to determine the comparative effects of the total rays from an ordinary gas radiator, dark heat rays from the same source, and total rays from a carbon arc lamp upon the temperature of the human subcutaneous tissue. We took the temperature of the tissues in some cases by placing delicate thermometers into the tissues, and in other cases by using thermo-electric couples mounted in hypodermic needles, connected with a differential galvanometer; for this apparatus we are indebted to our colleague, Dr. E. J. Schuster.

Results from Observations upon Rabbits.

Examples of our results from observations upon rabbits are given in Tables I. to VII. In most of these observations we employed urethane as an anæsthetic; the results were not obviously affected by the anæsthetic, since they resembled results from animals without anæsthesia. In some cases the whole body of the animal was exposed to the sun's rays (Tables I., II., and IIIA), whilst in other cases the head and upper part alone were exposed to the sun, the rest of the animal being shaded (Table IIIB). From Table I. it will be seen that exposure of the whole body of the animal to the sun for about half an hour raised the temperature of all the deep tissues about 1° C., whilst one hour's further exposure of the whole animal to the sun raised the temperature of all the deep tissues to above 41° C.; the rectal temperature of this animal in the shade before the

experiment was 38.2° C. The ear temperature was taken in all cases by wrapping the ear round a thermometer. The fur temperature of the animal was greatly raised—53° C. The animal's fur temperature, taken by stroking the fur to and fro with a thermometer, was a good guide to the intensity of the sun. For this purpose we also recorded the temperature of a piece of ordinary black fur exposed to the sun until its

temperature became almost constant. Table II. shows how the temperature of the animal continues to rise after death; the cause of death in this case was probably due to urethane. Tables IIIA and IIIB should be compared with one another. The results in Table IIIA were obtained from a grey rabbit, the whole body being exposed to the sun, whereas the results in Table IIIB were obtained at the same time from another grey rabbit, the head and upper part of the body being exposed, while the rest of the animal was shaded. Whereas the temperatures of the various deeper tissues showed a distinct rise of temperature in the former rabbit, in the latter there was distinct fall. In the former rabbit the respiration was much increased, being 108 per minute, whilst in the latter quite a normal figure was obtained, 60 per minute.

We may conclude, then, that exposure of the head and upper part of the animal to the sun probably caused on the whole a depression of metabolism. We must remember that the rabbit has no sweat glands. It is well known that this animal does lose heat easily from its ears, but such a mechanism obviously could be of little value when the fur temperature of the head was 46°C . in the sun. As we were not able to produce much local effect on the brain by the intensity of sun available—the fur temperature never exceeded 54°C .—we next employed the carbon arc, placing the animal head-on about 4 or 5 feet from the carbon arc reflector, the body of the animal being shaded. Tables IV., V., VI., and VII. give results from some observations. It will be noted that we obtained a distinct rise of temperature in the brain by the rays from the carbon arc when the fur of the head was heated above 60°C . Thus in Table IV., after 30 minutes' exposure, the temperature of the fur of the head was 61°C ., the temperature between the skull and dura mater was 41.5°C ., that of the cerebrum was 41°C ., whilst the rectal temperature was only 38.5°C . The effect of heating of the head and brain by this means caused a marked increase in rate of respiration, although the rectal temperature was not increased. Subsequent shading of the whole body of the animal was followed by a fall of temperature of the urethanised animal below normal—which is usually given as 38.5°C . for an ordinary laboratory rabbit. In Table V. it will be noted that exposure to the carbon arc produced the following readings: 69°C . for the fur of the head, 46°C . under the scalp, 43°C . between the skull and dura mater, 42°C . in the cerebrum, 40.5°C . in the medulla, whilst the rectal temperature, although showing an increase, was quite a normal figure, 38.5°C . Here, again, the respiration was much increased. In Tables VI. and VII. we give the results obtained from animals without an anæsthetic. They are very similar to the results during anæsthesia given in Tables IV. and V. The figures in Table VI. were 69°C . for the fur of the head, 42.5°C . for the cerebrum, taken immediately after killing the animal by a blow on the neck, 41.5°C . for the medulla, whilst the rectal temperature was 41°C .; and the figures in Table VII. were 67°C . for the fur of the head, 42°C . under the scalp, 40°C . in the cerebrum, and 38.5°C . in the rectum.

Our results are of interest in connexion with the pathological effects of insolation, as in sunstroke. This subject was dealt with by one of us (L. H.) in "The Science of Ventilation and Open-Air Treatment,"⁴ to which the reader is referred for the literature. Therein it is recorded that Aron killed monkeys by exposing them to the sun in the Philippines. They died with body temperatures reaching respectively 43.5° , 42.7° , 46.3° , and 44.8°C . None of our rabbits showed a higher rectal temperature than 42°C . Aron found that shading by an umbrella or a board prevented death, as did a brisk current from a fan. Death was due, then, to heat-stroke, and not to any lethal effect of light rays, a conclusion confirmed by the fact that monkeys enclosed in boxes, with the head only exposed, suffered no inconvenience, although their scalp temperatures reached 47°C . One of our rabbits showed 48°C . for temperature of subcutaneous tissue of the neck when exposed to the

carbon arc (Table IV.); another rabbit gave 46°C . under the scalp when similarly exposed (Table V.). None of our animals died during exposure.

Schilling⁵ also found the subcutaneous temperature of a white rabbit in the shade to be 38.4°C .; in the sun in 30 minutes it rose to 40.4°C . The skin was shaved, and after 30 minutes in the sun the temperature of the subcutaneous tissue was 41.5°C . Our figures for subcutaneous tissue temperatures were often higher than these, although our animals were not shaved. Schmidt⁶ exposed a white and a black rabbit to the sun. The rectal temperature rose from 38.5° to 39.5°C . in the white, and to 40.2°C . in the black, so that attention must be given to the fact that black fur absorbs more heat than white fur.

Three chimpanzees were exposed to full sun by accident in a court of a laboratory in French Guinea mid-day, between 12 to 2 o'clock. The temperature of the air was 40.6°C ., the relative humidity 20. The servants reported that they had noticed the agitation and plaintive cries of the animals. They were found as convulsions passed into muscular resolution, coma, and death. The conjunctivæ and skin were injected; there was no relaxation of sphincters; the pulse was accelerated and the animals died in spite of cold baths. The rectal temperature was 40°C . 15 minutes after death. Post-mortem examination revealed congestion of all organs, particularly the lungs, turgescence of venous sinuses of the brain, and presence of exudation in the pericardial cavity. There were signs of a destruction of leucocytes in the blood.⁷

Our results support the evidence that while so-called sunstroke is generally heat-stroke due to overheating of the body in general, overheating of one part of the body can be brought about by the sun or other source of radiant energy. Pith helmets, spinal pads, &c., prevent such local heating, which takes place to a greater extent in those exposed to the sun whose circulation is from any cause enfeebled. The perfectly fit man, just as the fit monkey, can become injured by training and suitable diet even to exposure of his whole body to the tropical sun, protected as he is by sweating and a good circulation.

Results from Observations upon Human Skin.

We have repeated, under somewhat varied conditions, Sonne's experiments, which deal with the power of luminous rays to heat up subcutaneous tissue and the blood therein above the surface temperature. For these observations we employed ordinary sources of rays—that is, the rays from a carbon arc lamp, red radiant heat from an ordinary gas radiator, and dark heat rays from the same source, the luminous rays being shut out by placing an iron sheet in front of the gas fire. Obviously the carbon arc possessed the most luminous and the dark heat the least luminous rays. The non-luminosity of the rays was tested by tube inspection under a dark cover. The thermoelectric needles of the differential galvanometer were placed under the skin and just below each knee, and one knee was exposed to the various rays, the other being shaded. When in each case the surface temperature had reached the just bearable temperature of 45°C .—as measured by a delicate surface thermometer—the reading of the differential galvanometer was taken. The differences between the temperatures under the skin of the two knees (L. H. June 27th, 1922) were 10.5°C ., 6.7°C ., and 6.3°C . for the carbon arc, ordinary gas fire and dark heat rays respectively, showing that the more luminous rays from the carbon arc affected the subcutaneous temperature to a greater degree than did the rays from the other two sources of heat. This supports Sonne's work, showing that luminous rays raise the subcutaneous temperature above that for the skin surface. It was found in our experiment just described that the temperature under the shaded knee was 33.5°C .—one needle was placed in water of a known temperature, and thus the differential galvanometer enabled us to calculate the exact temperature under the shaded knee where the other needle was placed. From this

it follows that the exact temperatures under the skin of the exposed knee were 44°C . ($33.5 + 10.5$) with the carbon arc, 40.2°C . ($33.5 + 6.7$) with the gas fire, and 39.8°C . ($33.5 + 6.3$) with the dark heat rays. Experiments with other subjects gave similar results. Thus with subject J. A. C. (June 29th, 1922), when the skin of the exposed knee showed a surface temperature of 45°C ., the temperatures under the skin were 12° , 10° , and 9°C . higher for the exposed knee than for the shaded knee with the carbon arc, gas fire, and dark heat rays respectively.

In other experiments we employed an insulated and coiled thermometer placed over the median vein in front of the elbow, whilst the hand was exposed to the rays from the same three sources. The temperature rose rapidly over the vein with any of the rays, showing that the blood in the hand was warmed by the rays. It was not possible by this method to show the comparative effects of the rays from the different sources, because the hand was also heated by the air, and this would affect the temperature of the blood in the median vein, although such a condition could not greatly influence the results with the hypodermic needles, as they were localised. We also found that when the forearm is exposed to the Alpine winter sun and to the cold atmosphere that the surface temperature of the median vein may rise $2-3^{\circ}\text{C}$. in five minutes.

Summary.

1. Exposure of the whole body of a rabbit to the sun's rays at Hampstead rapidly increased the temperature of the deeper tissues, the fur temperature rising as high as 54°C .

2. Exposure of the head and upper part of the body to the sun's rays was followed by a fall of temperature in the deeper tissues, the fur temperature in the sun not exceeding 46.5°C .

3. Local exposure of the head of a rabbit to the carbon arc greatly increased the temperature under the scalp and in the brain, the fur temperature rising above 60°C . The body temperature—rectum—was often not greatly altered. The respiration was always very rapid—over 100 per minute.

4. While recognising fully that heat-stroke is usually due to a general raising of the body temperature, our results show that local heating may occur, and confirm the utility of pith helmets and spinal pads on exposure to tropical sun.

5. Using the skin of the human knee and ordinary sources of rays—carbon arc and gas radiators—Sonnen's results were confirmed—i.e., luminous rays heat up the subcutaneous tissues to a greater degree than do non-luminous rays, the skin temperature being the same in both cases.

THE TREATMENT OF STUTTERING.

By E. W. SCRIPTURE, M.D. MUNICH, M.R.C.S.ENG.,
PHYSICIAN TO THE SPEECH CLINIC, WEST END HOSPITAL
FOR NERVOUS DISEASES, LONDON.

STUTTERING or stammering is usually regarded as incurable, and not more than 5 per cent. of treated cases ever fully recover, for the pathology of the disease has never been established, and no rational methods of treatment have been found.

The Pathological Lesion.

The first step is to locate and define the pathological lesion. For years I have been attempting this by means of speech inscriptions. In this method of research the patient speaks into a recording apparatus that registers the puffs and vibrations of speech on the moving surface of a blackened drum. The record

sheet is afterwards removed and studied, and measured under the microscope.¹ The detailed results of the investigations lead to certain conclusions.

In the first place the speech inscriptions show that stuttering does not involve any lesion or abnormality of the organs of speech as part of its pathology. Most important of all is the proof that stuttering does not depend on any lesion of the nerves, of the bulbar centres, of the mechanisms of *taxia* or *synergia*, or of any form of nervous coördination. The theory of Kusmaul, Gutzmann, and others, that stuttering is a trouble of nervous coördination of the muscles, has no foundation, and the theories that it depends on defective breathing or tongue action are contrary to fact. In the inscriptions of stutters there is one peculiarity that is never lacking, even in the speech of a patient when he is apparently not stuttering. The stutterer shows a special type of the melody of speech. No such form of the melody of speech is found in any nerve or brain disease or in any mental disease, even of the milder types such as hysteria, psychasthenia, or early dementia præcox. It has, however, two resemblances, on the one side to the speech of normal persons in a certain condition of mind, and on the other side to the speech of epileptics. As I have shown in studies of the speech of epileptics,² the condition common in these three cases is an emotional resistance to the situation, a negation of yielding to the environment. When the environment is changed so that the objectionable element is removed, the peculiarities in normal speech, epileptic speech, and stuttering disappear.

The vital point is next to determine the nature of the objectionable element that affects the speech. In normal life it is anything that arouses a feeling of opposition. With the epileptic it may be the entire content of life. The stutterer has no objection to the events of life, yet when he finds himself alone, his stuttering disappears. It is to be understood, of course, that the objection in all these cases is unconscious; the epileptic or the stutterer himself knows nothing about them and would deny the fact if it were told him. There may be the usual conscious over-compensation for the unconscious defect; the epileptic or the stutterer may attempt to be even more sociable than normal.

Necessary Alteration of the Mental Condition.

If stuttering is a resistance to the human element in the environment, its location is mental, and the aim of the treatment should be to alter the mental condition. Consider the following emergency: A very bad stutterer is called upon to deliver a public lecture before an august body, and on account of his trouble his address will have to be read by someone else. In such a case the stuttering can be temporarily cured for a few days by making a slight but somewhat painful cut in the tongue, by burning it slightly with a cigarette end, by holding a sharp pebble in his mouth, or by any other device that will make his tongue feel painfully queer. The explanation is a curious one. He is now a person in pain, and the human environment may go hang. Another emergency is that of the stutterer who cannot or will not undergo rational treatment but wishes to have occasional help in important situations. If he has sufficient force of character to be willing to speak in what he considers a queer voice, he can speak fluently whenever he pleases. The explanation is that he now feels himself to be a personality of a different kind. This phenomenon is illustrated by the following case: The head of a large business department stuttered so that he could not dictate to his stenographer; he always wrote out his letters and then handed them to her. This he kept carefully concealed from his superiors. On beginning treatment he was told to sing; he had no ear whatever and simply spoke along on about one tone in practically normal speech

¹ The method has been repeatedly described in Brain, Quart. Jour. of Med., Proc. Roy. Soc. Med., Jour. of Neurol. and Psychopath., and also in my Stuttering and Lispings.

² Proc. Roy. Soc. Med., 1920, vol. xiii. (Psychiatry), p. 18.

although he believed he was singing. He was now told simply to sing his letters to the stenographer and that all would be well. He refused, saying that he did not wish to make a fool of himself by singing to his stenographer. The result was "no thoroughfare." It could not be explained to him that he did not really sing when he thought he was doing so, for the entire efficacy of the method lay in his belief that he was singing.

Abnormal Melody of the Stutterer's Voice.

The situation can be helped by demonstrating to the stutterer that he always—even when not stumbling—speaks with an abnormal melody that seems natural to him, but that is really abnormal. Then he is shown that he can speak perfectly in any abnormal way—e.g., in a dialect, with long vowels, on a high note, &c. Finally he is shown that he can also speak perfectly when he adopts a melodious manner of speaking. He will object that when he speaks so melodiously he speaks queerly. It must then be shown to him that when other people speak melodiously the speech does not sound queer. He must grasp the fact that his own abnormal speech appears normal to him but abnormal to others, and that although melodious speech sounds abnormal to him, it sounds normal to others. If he can do this, and has character enough to carry out instructions, he can speak perfectly whenever he wishes. Any rational cure must be aimed at correcting the fundamental psychic defect.

The Combating of Fear.

First, the stutterer's opposition is to be combated, but to tell the patient about his attitude of opposition or of the need of changing it is absolutely contra-indicated. His opposition is unconscious and unknown to him and he will disbelieve and resent any such statement. The chief cause of opposition is the feeling of fear, which can be combated in several ways.

An obvious method of combating the fear is to readjust the patient's environment. In nearly all cases of stuttering children some disturbing influence will be found in the family circle; one boy stood in dread of a vigorous and domineering father, and trembled whenever the father spoke. A school away from home was advised. Many a boy is so coddled, so dependent on his mother, that no result can be hoped for until he is removed from her. The influences in a child's life can be fully understood only by persons familiar with the psychology of the unconscious.

A second method is to get at the root of the fear by psycho-analysis. This alone is not adequate, and no stutterer has ever been cured by it. The patient has a whole series of bad habits engrafted upon his fear, and he will not drop them unless he is shown how to do so. The usual methods of psycho-analysis can often be most profitably modified with stutterers. It is to be remembered that the stutterer comes for relief from his speech trouble, not for the readjustment of his nervous condition. Many such patients resent the slightest discussion of sex topics. If it were necessary to perform an elaborate psycho-analysis in order to cure stuttering, the difficulty would have to be faced, and the patient would have to submit or go away, but this is fortunately not the case. Two of my patients, a boy and a girl, found relief by merely talking about family affairs. Sexual matters were never mentioned, the chief weight being laid on other methods.

Still another method lies in exercises that will combat fear in general and fear in speaking in particular. Such forms of outdoor sports and gymnastic exercises are to be selected as will, in the particular person, best produce a feeling of power and superiority. A similar feeling in meeting an opponent may be favoured by boxing and fencing. Breathing exercises often help to give confidence in speaking. Of the utmost importance are exercises in melodious speech, in rhythm, in expression, and so on. The exercises in themselves are worthless; it is the specialist's use of them to develop confidence that is the active principle. The administration of glandular substance from the suprarenal cortex has been favourable in

examples of timidity, but the best success is attained when it is combined with thyroid and pituitary.

The Stutterer in a Speech Clinic.

The case of a stutterer in a speech clinic or a special school class is not so hopeless as it might appear, but to treat a whole class by one form of exercise is like treating a surgery full of people from one supply-bottle. Again, to submit a whole class to many exercises is no more rational than to dose the whole surgery with all the medicines of the dispensary indiscriminately. The variety of the effect does not counteract the patient's confusion and loss of confidence. A class or a speech clinic should be handled exactly like a crowded surgery. Each patient should be seen separately every time, and should receive a prescription for the particular exercises or other treatment that he may need at the time. The exercises themselves can be carried out by proper assistants. The head of a speech clinic is necessarily a physician; no layman can conduct it, any more than a nurse can run an orthopaedic clinic. The treatment of stuttering is a medical affair and can be handled only by a medical man.

Clinical and Laboratory Notes.

CASE OF INVERTED PYLORUS OBSTRUCTING A GASTRO-JEJUNOSTOMY APERTURE.

By JAMES MCCLURE, F.R.C.S. ENG.,
SURGEON, LONDON TEMPERANCE HOSPITAL;
AND

H. ETHELBERTA CLAREMONT, M.S., F.R.C.S. ENG.,
SURGICAL REGISTRAR TO THE HOSPITAL.

A SEARCH in the literature has failed to reveal a report of any case similar to that described below, and as it illustrates a danger to be avoided, we think that it may not be without interest to those engaged in the practice of gastric surgery.

Post-mortem examination of a woman, aged 22, revealed the following remarkable condition: The pylorus had evidently been divided surgically at a previous date, and a posterior gastro-jejunostomy had been performed. There was an interval of about 2 in. between the pyloric end of the stomach and the duodenum, and in this interval the liver was adherent to the pancreas. On separating the adhesions the pancreas came into view. The proximal and distal ends of the divided pylorus had been invaginated, but whether any portion had been removed it was impossible

Diagram showing anatomical relationships of the inverted pylorus.

to determine. On opening the stomach along the lesser curvature, the invaginated portion of the pylorus was seen to be about 1½ in. in length, hanging down in the form of a pedunculated polyp into the gastro-jejunal aperture, and almost but not quite blocking it (see diagram). No ulcer was found in any part of the stomach or jejunum. The polyp was freely movable and was neither swollen nor oedematous, but it is conceivable that during life congestion of the polyp with some spasm of the gastro-jejunal stoma had from time to time occurred, producing intermittent obstruction of the orifice. Congestion might also have led to hæmatemesis, and thus it is possible to explain the puzzling symptoms presented by the patient before her death. She was admitted to hospital 13 days before she died with a history of gastric trouble of eight years' duration—i.e., commencing at the age of 14. Two operations had been performed, in May, 1918, and in June, 1922, respectively but with temporary relief only, persistent epigastric pain accompanied by vomiting and hæmatemesis making her life one of misery and incapacity. She had never been able to undertake any serious work and had spent long periods ranging from 7 weeks to 14 months in bed on a milk diet. Even after admission to hospital, when all food by the mouth had been stopped,

she continued to vomit. Life was maintained for some days by means of rectal salines and glucose, but her condition was too precarious to permit of further surgical intervention.

The case is reported to illustrate the danger of invaginating too long a portion of gut and thereby forming a polyp. In this case it caused an obstruction to the outlet from the stomach, and it is possible that in other situations—for example, in a lateral anastomosis after resection of intestine—a terminal invaginated portion might similarly be a potential source of obstruction.

CASE OF TORSION OF AN OVARIAN CYST IN AN INFANT.

BY E. M. POWELL, M.R.C.S. ENG.,

LATE HOUSE SURGEON, EVELINA HOSPITAL FOR CHILDREN,
LONDON, S.E.

THE following case may be of interest as an example of an unusual condition occurring at an early age.

A female infant, aged 5 months, was admitted to the Evelina Hospital for Children with the following history. Fourteen days before admission she had an attack of vomiting and abdominal pain, which passed off in 24 hours; four days before admission she vomited a quantity of dark brown material and refused to take the breast. She seemed to be in great pain, and was very constipated.

Condition on Examination.—When first seen at hospital the child looked extremely ill. She had a rectal temperature of 101° F. The abdomen was much distended, and per rectum there was blood on the examining finger. Resistance was felt above and in front of the rectum. On re-examination under an anæsthetic a tense, cystic tumour was found, about the size of the foetal head, filling the abdomen and part of the pelvis.

Operation.—A laparotomy was performed, and the cyst was found to have a twisted pedicle; one twist included the right Fallopian tube, a second twist the uterus, with the left tube and ovary. The uterus and appendages were dark purple in colour, and had to be removed entire. The abdomen was closed without drainage. The patient's condition at the close of the operation was good, and she has made an uninterrupted recovery. She is remaining in hospital while the possibility of ovarian grafting is under consideration.

Specimen.—The specimen removed proved to be a unilocular cyst (see illustration), with a thin, smooth wall,

Ovarian cyst with twisted pedicle; one twist included the right Fallopian tube, the other included the uterus, left tube, and ovary. Note the two cysts (the size of peas) in the left ovary.

containing a serous brown fluid. It had apparently entirely replaced the right ovary. The left ovary also contained two cysts, the size of peas. The wall of the uterus was full of extravasated blood, and the organ had evidently been strangulated for some time. Microscopically, no trace of an epithelial lining could be found remaining in the cyst; there were several hæmorrhages into its walls from congested vessels.

I have to thank Mr. W. E. Tanner for his kindness in allowing me to publish this account.

Rebiews and Notices of Books.

AN INDEX TO GENERAL PRACTICE.

By A. CAMPBELL STARK, M.B., B.S. Lond., L.S.A.,
Ph.C. London: Baillière, Tindall and Cox. 1923.
Pp. 181. 5s.

Dr. Stark describes his book as a humble effort to help the general practitioner in his daily work. He comments on the curious fact that although a large majority of medical students go into general practice, no attempt is made during their curriculum to train them for their special work. Yet, he adds, the work of the general practitioner differs considerably from that of his teachers of medicine and surgery. Writing as a general practitioner himself, he frankly admits that some part of general practice must be a compromise between what it is best to do for the patient and what it is possible to do; and within the brief compass which he has allowed himself Dr. Stark sets out what he has himself found both good and possible in his own experience and after a considerable number of trials and errors. The book is dogmatic in the sense that it is largely a record of convictions deduced from experience. Dr. Stark takes a keen personal interest in his patients; he has learnt to understand and sympathise with their point of view; he evidently enjoys his work and finds satisfaction therein: his dogmatism is the mellowed expression of experience and as such will be welcome to the beginner in general practice. The book is arranged under a series of subject headings in alphabetical order, beginning with Alcoholism, Anæsthetics, Antiseptics, Babies, Birth Control, Blood Pressure, and Books. The section on Books is less than five pages long, but contains much sound advice. Dr. Stark deprecates the accusation brought against the general practitioner that he does not read, and he has drawn up a list of some dozen books which illustrate the principle that the most important things in general practice are personal observation and experience. The selection is felicitous and closely resembles what we have ourselves found useful. Chapters on medico-political and medico-ethical matters are as helpful as those dealing with technique. No embryo general practitioner can fail to derive some hints from the sections on Consultants, Fees, Panel Practice, Practice in Relation to the Law, the Patient and the Public. Nearly every section has its own brief bibliography with a suggestion for further reading. The book is sound and useful, and we congratulate the author upon it.

TECHNIK UND METHODIK DER BAKTERIOLOGIE UND SEROLOGIE.

Von Prof. Dr. M. KLIMMER, Obermedizinalrat,
Direktor des hygienischen Instituts der Tierärztzl.
Hochschule, Dresden. Berlin: Julius Springer.
1923. With 223 illustrations. Pp. 520. 11s. 8d.

THIS is a handbook of reference for laboratory workers and deals with the investigation of material from both human and veterinary sources. The methods described are concerned almost entirely with routine diagnosis and public health work, including the bacteriological examination of water and milk. Regulations and procedure required for taking, sending, and dealing with specimens and pathological samples are detailed, and there are good chapters on sterilisation, filtration, microscopy, staining, section cutting, and animal inoculation. There is a full account of the preparation of different kinds of culture media and of methods of cultivation. Twenty pages are occupied with the testing of disinfectants. The information about special micro-organisms is to be found in a convenient form as an alphabetical list occupying about 50 pages. A section or paragraph is devoted to each organism, and the chief criteria for their diagnosis; cross references are given to pages on which the methods involved are described. The commoner protozoa are briefly included with bacteria and spirochaetes, a longer section being taken up with entamœbæ, but scarcely any mention is

made of helminths. There are some omissions—e.g., the *Micrococcus melitensis*.

The chapter on serology gives detailed methods for preparing diagnostic sera, but no reference is made to the manufacture of therapeutic sera. The techniques of agglutination and precipitin reactions are clearly described, as well as the various uses of complement fixation. The Sachs-Georgi and Meinicke reactions are shortly but clearly dealt with, and there are sections on the application of allergy, and anaphylaxis to the diagnosis of unknown proteins or bacterial substances, and infections. The tuberculin and mallein tests are very briefly treated, no doubt, because they belong to the department of the clinical rather than the laboratory worker.

No attempt is made to discuss scientific principles or current hypotheses. The limited scope of the book in this direction is indicated by the absence of all allusion to different types of meningococcus, pneumococcus, or proteus X19, &c., or to the Schick test for diphtheria immunity. The importance of bacterial carriers is alluded to only in the official regulations quoted, though the kind of laboratory for which the book is intended must be largely concerned with a search for carriers. On the whole the book appears to be a useful and accurate guide to ordinary technique and apparatus with a considerable choice of methods, but with little advice as to their relative advantages. A large number of references (as foot-notes) to original descriptions of method by German, American, English, and French writers considerably enhances its value.

MOLECULAR PHYSICS.

Third edition. By JAMES ARNOLD CROWTHER, M.A., Sc.D., F.Inst.P., University Lecturer in Radiology; Demonstrator in Experimental Physics at the Cavendish Laboratory, Cambridge. London: J. and A. Churchill. 1923. Pp. 189. 7s. 6d.

THE third edition of Dr. Crowther's book certainly fulfils the author's purpose of presenting in a coherent and intelligible fashion a brief account of the electrical theory of matter. The task is accomplished in a particularly attractive manner; there is always an attempt to visualise the processes which are being described. The author's impartiality serves him well; there are excellent accounts of the completest agreement with theory and fact, notably the variation of effective mass of the electron with its speed, the quantum relation of Planck and Bohr's recent "theory of action" in its application to spectroscopic phenomena, while difficulties are not shirked. Dr. Crowther has a way of taking the reader right up to the existing boundaries of knowledge and then letting him know how difficult it is in some places to reconcile the facts with the theories advanced to explain them.

The arrangement of the subject-matter is excellent, the diagrams are well chosen, and the style in which the whole book is written is happy. It is safe to predict that the third will not be the last edition.

X RAY DOSAGE IN TREATMENT AND RADIOGRAPHY.

By WILLIAM D. WITHERBEE, M.D., Radiotherapist, Presbyterian Hospital, New York; and JOHN REMER, M.D., Radiotherapist, New York Hospital. New York: The Macmillan Company. 1922. Pp. 87. 8s.

THE method of dosage described in this book has been used by the authors in clinics and private practice for the past four years. They regard the system of dosage "as safe within certain limitations—namely, between a 3- and 10-inch spark gap and between 6 and 20 inches distance." On the whole, this claim seems to be justified and the method is practical as far as a formula method can be. The system gets rather complicated with screened exposures, but no doubt this complication tends to simplify itself in the brain of the operator, though by that time his need of any rigid system may be less. Considerable stress is laid on the fact that the skin dose resulting from a number of exposures for the purposes of

skiagraphy can be estimated by the formulæ given and the danger of accidents avoided. The authors claim no knowledge of the recent method of treating cancer by the use of high voltages.

The little volume is of the notebook type and as such is likely to be very useful.

THE NEW PSYCHOLOGY AND THE PARENT.

By H. CRICHTON MILLER, M.A., M.D., Editor "Functional Nerve Disease"; Hon. Director, Tavistock Clinic for Functional Nerve Cases. London: Jarrolds. 1923. Pp. 255. 6s.

THIS is a combination of advice to parents with the author's views on the new psychology—a useful term which allows writers to accept what of modern theories seems pleasing to them. In this case the new psychology is mainly that of Jung, with due acknowledgment of the work of Freud, and Dr. Crichton Miller makes this popular statement of principles because it seems to him worth while that psychologists should make good their attitude in the eyes of the intelligent and unprejudiced section of the public. With this aim it is perhaps justifiable to present his subject in a somewhat didactic manner and avoid many of its intricacies. But the simplicity thus attained is dangerous; the chapter on dream symbolism, for example, leaves the impression that interpretation of the dream is entirely a matter of ingenuity on the part of the analyst, and such a false impression should be avoided by the propagandist. The practical teaching of the book, however, is sound and useful; the theory of the unconscious has important application to the relationship between parent and child, and this application is intelligibly explained.

THERAPEUTIC LEXICON.

Lexikon der gesamten Therapie des praktischen Arztes, mit Einschluss der therapeutischen Technik. Second edition. Edited by WALTER MARLE (W. Guttman). Berlin and Vienna: Urban and Schwarzenberg. 1923.

WE have received the third part, being pages 321 to 480, of this therapeutic lexicon, which aims at being a compendium of modern medical technique. The whole work is to be completed in 15 parts, which later can be bound in three volumes. The contributors include the names of the most distinguished physicians and surgeons in Central Europe. The scope may readily be indicated by citing a few consecutive subject headings—e.g., Glandular fever, Duodenal ulcer, Dupuytren's contraction, Thirst (increased and diminished), Douching, Douche-massage, Arteriosclerotic dysbasia, Dyshidrosis. It may be instructive to take one subject as dealt with in this lexicon and compare it with one of the series of special articles on Modern Technique appearing in our own columns. Take, for instance, epilepsy, on which Dr. Gordon Holmes wrote in THE LANCET of March 10th. Dr. Th. Becker finds it necessary to precede his account of treatment by a short section on differential diagnosis and the varieties of epileptic manifestations. It is curious that he should have to issue a warning against the popular practice (here only current amongst school-boys) of prising up the patient's thumb-nail during an attack in order to distract his attention. He gives bromide in the form of the sodium salt, the Sandow salt, or the Erlenmeyer mixture, combining it with a salt-limited diet, and for some time past has combined these two objects in his own practice by prescribing sedobrol (Roche), which is a combination in tablet form of bromide with soup extract. He first tests the patient's bromide tolerance by giving up to four to five tablets a day, gradually reducing to zero by omitting one tablet a day, dropping a week, and then slowly increasing again. He has succeeded in this way in freeing completely from their periodic attack a number of severe cases. Flechsig's opium-bromide treatment he regards as archaic, and he has had no success with Rosenberg's epileptol, for which high claims have been made. Of drugs, apart from

bromide, he mentions only zinc oxide and atropine, the latter in doses of 0.2 to 0.5 mg. Prophylaxis for threatened individuals Dr. Becker regards as of the first importance, the tendency to hereditary transmission being so strong that marriages of epileptics, if entered upon, should remain sterile. Total abstinence from alcohol, regular daily action of the bowels, and non-stimulating nourishment are the points on which he lays stress, as well as limitation of salt in the diet. A useful list of institutions for epileptics completes the article.

DISEASES OF THE LIVER.

Physiologie normale et pathologique du foie. By G. H. ROGER, Doyen de la Faculté de Médecine de Paris, Professeur de Pathologie Expérimentale et Comparée, Membre de l'Académie de Médecine. Paris: Masson et Cie. 1922. Pp. 400. Fr.22.

THIS book deserves a wide audience, and should be read with special interest by those who last year welcomed the learned Dean of the Medical Faculty of Paris when he addressed a London University audience. Prof. Roger writes with lucidity and understanding, and summarises our present-day knowledge of the physiology of the liver in health and disease. His book, also, forms a valuable treatise on the mechanism of the production of immunity, and is a fitting continuation of the work which its author began under the inspiration of Claude Bernard.

Traité de pathologie médicale et de thérapeutique appliquée. Vol. XII.: Foie et Pancréas. Second edition. By J. CASTAIGNE, BRULÉ, GARBAN, NOEL FLEISSINGER, FAROY. Paris: A. Maloine et Fils. 1923. Pp. 522. Fr.22.

THIS volume is one of the most attractive yet published in this system of pathology and therapeutics. Prof. Castaigne deals clearly with the general problems of hepatic disorder and emphasises the importance of modern laboratory methods. Prof. Noel Fleissinger sets out the clinical facts with regard to the cirrhoses and treats of their general pathological effects in a manner which is original and suggestive. Other subjects, such as gall-stones and hepatic abscess, contain excellent epitomes of the doctrines of the French School of Medicine. The portion of the book which deals with the pancreas is less attractive; little mention is made of the connexion of the pancreas with diabetes, and when it is said that no reference is made to the work of Allen, of Opie, or of Banting and Macleod, the significance of the omission will be understood.

A DICTIONARY OF APPLIED CHEMISTRY.

Vol. IV. By Sir EDWARD THORPE, C.B., LL.D., F.R.S. London: Longmans, Green and Co. 1922. Pp. 740. 60s.

THE fourth volume of this well-known and important work, which starts at "L" and concludes with "Oxydisilin," well maintains the high standard of the previous volumes. The contents of the dictionary have been carefully revised so as to accord with recent developments of chemical science. Many new articles have been added, and certain of the existing articles have been re-cast or re-written. Fine chemicals have been the subject of special attention, the pharmacological articles have been revised, alkaloids and synthetic drugs have been treated at greater length, and a considerable amount of new matter relating to them has been added.

There is much which is of interest to the medical man in the present volume. Thus Dr. E. F. Armstrong writes on the enzymes, lactase, lipase, maltase, and the oxydases; Prof. G. Barger on laudanum, liquorice root, nicotine, and other alkaloids; Mr. C. T. Bennett on essential oils; Mr. J. Connah on liqueurs and cordials; Mr. Cribb on spices; Mr. C. A. Mitchell on oils, lard, and margarine; Mr. H. D. Richmond on milk; Mr. F. Scudder on meat extracts; and Dr. H. E. Watt on nux vomica and opium.

CHEMICAL REACTIONS AND THEIR EQUATIONS.

By I. W. D. HACKH, Ph.C., A.B., Professor of Biochemistry, College of Physicians and Surgeons of San Francisco. London: Chapman and Hall. 1922. Pp. 138. 6s.

THE difficulty which students have in fully appreciating chemical equations is well known to teachers of chemistry. The present volume has been written with the object of assisting a clearer understanding of the principles of chemistry so that the student should be enabled to balance any equation with care and rapidity. The subject-matter deals with symbols, formulæ, equations involving oxidation and reduction and the converse, reactions and their control, and types of chemical reactions and equations. The information presented is concise and free from errors.

LEHRBUCH UND ATLAS DER GASTROSKOPIE.

By Dr. med. RUDOLF SCHINDLER, Assistenzarzt der 2 med. Abteilung des Krankenhauses Munchen-Schwabing. Munchen: J. F. Lehmann. 1923. Pp. 132. 9s. 7d.

IN this book the author deals with the problems and possibilities of gastroscopy. Available types of instrument are described, and the technique of securing a complete examination of the internal surface of the stomach is fully gone into. The volume is illustrated by 20 coloured plates showing the appearances seen in gastritis, ulceration, malignant disease, and after gastro-enterostomy. It is impossible to read it without being deeply impressed by the possibilities of gastroscopy, and it is to be hoped that the subject will soon obtain wider notice in this country. The size, paper, and binding of this book are of a quality which makes the price demanded an exorbitant one; this is the more striking in view of the present rate of exchange with Germany.

A HANDBOOK OF NURSING.

Eighth edition. By M. N. OXFORD, formerly of Guy's Hospital. London: Methuen and Co., Ltd. 1923. Pp. 312. 6s.

Miss Oxford's Handbook of Nursing, which has reached its eighth edition, can be highly recommended to probationers in training. Young nurses may often be confused with the multiplicity and variety of new duties on entering hospital training, and this manual may help them considerably in understanding their work. Chapters which will be found specially useful are those on What to Observe in Nursing, Infectious Diseases, Monthly Nursing, and X Rays. The value of the short chapters on Anatomy and Physiology would have been enhanced by the addition of some clear illustrations. Miss Oxford's aim to supply in as simple a form as possible the knowledge essential for the comfort and care of the sick has undoubtedly succeeded, and the book should inculcate in young probationers the principles which underlie all good nursing.

OXIDATIONS AND REDUCTIONS IN THE ANIMAL BODY.

Second edition. By H. D. DAKIN, D.Sc., F.I.C., F.R.S. London: Longmans, Green and Co. 1922. Pp. 176. 6s.

Dr. Dakin clearly states the object of this monograph in one of the opening sentences of the introduction, where he says, "The statements that fats and carbohydrates are oxidised to carbon dioxide and water are no longer considered all-sufficient explanations of the chemical rôle of these substances in the animal economy." Unfortunately, this statement is only too common both among teachers and students. Metabolism has been studied and taught far too much from the anabolic standpoint. Thus, after an amino-acid has been de-aminised we lose all interest in it, dismissing it with the statement that carbon dioxide and water are the end-products. To show the complexity of oxidising reactions in general the author takes the apparently simple case of the burning of carbon

monoxide in air. That the reaction does not proceed according to the well-known equation $2\text{CO} + \text{O}_2 = 2\text{CO}_2$ is proved by the fact that water is an essential participant in the reaction. Furthermore, various observers have isolated formic acid and hydrogen peroxide as by-products. That such an apparently simple reaction should prove so complicated makes the physiologist and biochemist wonder what stages are passed through when fats and carbohydrates are oxidised. Dr. Dakin takes each group of food substances, as well as various bodies of biological importance, and traces the changes undergone by them in the body.

This volume, small as it is, forms a valuable addition to the series of monographs on biochemistry and will open up an entirely new field for many readers.

JOURNALS.

JOURNAL OF PATHOLOGY AND BACTERIOLOGY. April, 1923.—Robert Muir (Glasgow): Obituary Notice of James Ritchie, Professor of Bacteriology in the University of Edinburgh, Secretary of the Society, 1906-1921, and Editor of the Journal 1921-23.—S. P. Bedson (London): The Genesis of the Mammalian Blood Platelet. Studying the regeneration of platelets after the administration of a lytic serum, the author concludes that they do not arise from red corpuscles or leucocytes, but are an independent element, originally nucleated like the thrombocytes of birds but losing their nuclei at maturity, as do red cells. In another paper on immunity to antiplatelet serum the same author shows that this is not due to the development of an anti-antibody, the existence of which becomes more and more doubtful.—T. Toda (London): An Attempt to Group Human Platelets with Red-cell Grouping Sera. Results altogether negative.—J. Ségel (London): A Fungus Isolated from Guinea-pigs Inoculated with the Virus of Typhus Fever. The fungus and virus show a remarkable association in passage through a series of animals.—S. C. Dyke (London): The Passage of *Staphylococcus aureus* through the Kidney of the Rabbit. The organisms pass into the urine only when they have definitely damaged the kidney.—W. E. de Korte (Cape Town): A Paramycetoma (?) of the Forearm. A subcutaneous nodule developing after a slight injury showed marked overgrowth of epithelium and what is apparently a filamentous fungus.—E. M. Dunlop (Glasgow): The Wassermann Reaction in Scarlet Fever. There is no evidence that scarlet fever ever causes a positive reaction.—R. P. Smith (Glasgow): The Relationship of the Autolysin and the Wassermann Antibody in the Serum of a Paroxysmal Haemoglobinuric. The two properties of the serum are distinct.—E. M. Luce (London): The Size of the Parathyroids of Rats and the Effect of a Diet Deficiency of Calcium. Rats fed on a diet deficient in calcium show a consistent hyperplastic enlargement of the parathyroids.—V. Korenchevsky (London): The Influence of Removal of Sexual Glands on the Skeleton of Animals Kept on Normal or Rickets-producing Diets. Castration has no effect on bone-growth in rats.—The same author describes an outbreak of spontaneous rickets among laboratory stock rats due to careless feeding; bacteriological investigations lent no support to Morpurgo's infectious hypothesis.—S. R. Gloyne and D. S. Page (London): The Reaction to *B. tuberculosis* in the Albino Rat. Rats are naturally highly resistant to tuberculosis, though after injection the bacilli are absorbed and spread in the body much as they do in the susceptible guinea-pig; virulent organisms may be recovered from the tissues after several months. Rat serum has no special bactericidal properties, though phagocytosis is extremely efficient.—J. M. H. Campbell, G. H. Hunt, and E. P. Poulton (London): An Examination of the Blood Gases and Respiration in Disease, with reference to the Cause of Breathlessness and Cyanosis. The authors have made an extensive investigation of cases of heart disease, anæmia, polycythæmia, primary functional deficiency of the lung and cardio-renal disease, correlating the

laboratory findings with the clinical condition. The value of the work lies mostly in details, for which the original must be consulted. Generally the authors conclude that peripheral venous stasis is nearly always a factor in cyanosis as well as deficient arterial oxygenation, and that bronchial spasm is the most potent cause of breathlessness.—F. G. Macnaughton (St. Andrews): A Simple Emergency Medium for the Primary Growth of the Gonococcus. Blood clotted in ordinary broth.—L. Cobbett and D. Keilin (Cambridge): Mucoid Casts from the Vermiform Appendix. A curious case in which a large number of small spherical masses of mucin filled the appendix.—R. Donald (London): Rapid Histological Sections, Gelatin Embedded and Fixed Throughout the Preparing: Diathermy Excision of Diagnostic Pieces; A Simple Modification of Twort Staining; A Syrup-gelatin Mountant; A Slide Index Box.

New Inventions.

AN EMPYEMA TUBE.

I HAVE recently modified the empyema tube devised by W. Turner. The spear point of the trocar has been shortened; the innermost opening of the cannula has been retained and enlarged, and the two other lateral openings have been dispensed with, and the small oval sliding shield has been enlarged, its greatest diameter being now $3\frac{1}{2}$ inches, and reversed so that its concave surface now fits the convex chest wall. The additions are a tap fitted to the outer end of the cannula, to which a side-arm has been attached; and a small metal tube, with tapered plug to fit the tap. The tube allows of irrigation of the pleural cavity, either intermittent or continuous. These alterations are shown in the illustration. In use the

cannula is passed through a rubber disc, which is the shape of, and rather larger than, the shield. The rubber disc fits the cannula tightly and lies against the concave surface of the shield. Rubber tubing connects the side-arm with a suction apparatus, which is set working. The trocar and cannula are pushed into the chest through an intercostal space. The shield is clamped at a level permitting the cannula to project into the empyema cavity for not more than one inch. The trocar is withdrawn and the tap is shut at once to prevent any serious entry of air. The pus escapes, through the side arm, into the suction apparatus. The shield and rubber disc are fixed tightly to the chest with tapes and strapping. To irrigate the cavity, the outer end of the metal irrigating pipe is connected by rubber tubing with the reservoir of lotion. The tap of the cannula is opened and the irrigating tube is inserted into the cannula until its tapered end plugs the opening in the tap. The lotion drips or spurts according to the degree of pressure employed into the cavity. The mixture of pus and lotion is sucked through the side arm by the evacuating apparatus.

The instrument has been made for me by Messrs. Allen and Hanburys, Wigmore-street, London, W.

THE LANCET.

LONDON: SATURDAY, APRIL 14, 1923.

ACCURACY IN DISPENSING.

AT the recent Guildhall Conference of bodies interested in National Health Insurance anxiety was expressed by representatives of approved societies lest panel patients were receiving drugs inferior in quality to those dispensed for private patients. We indicated at that time how little gravamen this charge has, inasmuch as the standard quality of each individual drug is necessarily that of the British Pharmacopœia. The discussion has since shifted from quality to quantity, and wide publicity has been given to certain evidence that dispensing lacks the necessary accuracy, with the result that insured persons do not get the quantity of the drug ordered. Dr. G. CLARK TROTTER, medical officer of health for Islington, pointed out in our columns that having occasion to test the dispensing of quite a simple prescription, he found that 6 out of 17 pharmacists fell short of accuracy, even when no account was taken of slight discrepancies. In a letter which we publish this week, Dr. J. P. WALKER, county medical officer of health for the Isle of Ely, gives further evidence of large discrepancy in the dispensing of a simple prescription containing glycerine and potassium iodide, the error running up to 20 per cent. or more, generally on the minus side. This, it should be added, was ten years ago, and the episode is noticed to indicate that a certain tolerance of irregularities may have been present for a long time. At the North London police-court recently a fine of 2 guineas was inflicted for supplying a bottle of physic deficient in sodium salicylate to the extent of 8.4 per cent., the pharmacist pleading in extenuation that the deficiency was small and that he was pressed for time. At the same court another pharmacist was charged with issuing a mixture deficient in potassium bromide to the extent of 27.1 per cent., the case being postponed for a further analysis. In other cases a prescribed ingredient was shown to be absent. At Salford a chemist was fined £3 for substituting a pill containing aloes and myrrh for aloes and iron, pleading a too casual glance at the prescription. At Hackney a pharmacist was fined 20s. and 10 guineas costs for selling a compound known in the London Insurance Pharmacopœia as Mist. Gent. Co., totally deficient in chloroform and hydrocyanic acid.

In regard to the Islington cases of defective dispensing the President of the Pharmaceutical Society of Great Britain wrote regretting that charges should have been brought publicly by a member of the medical profession against pharmacists, seeing therein an attempt to create antagonism between the medical and pharmaceutical professions. The Secretary of the Retail Pharmacists' Union also wrote to assure us that the general standard of accuracy in dispensing is satisfactory, and that the Union, through its Pharmaceutical Committee, is coöperating with the authorities in securing the highest possible standard for insurance prescriptions. We note that the Union has since issued a large displayed advertisement setting forth the high standard of training to which the pharmacist

is subjected, and pointing out that among 30 million prescriptions dispensed last year by the 5700 chemists belonging to the Union, only 11 were the subject of prosecution for faultiness, four of the charges being withdrawn. We hasten to assure both these professional associations that we were no party to a general charge of inaccuracy against practising pharmacists. But we regard the evidence as conclusive that certain pharmacists have not dispensed certain prescriptions with the accuracy which may reasonably be required of them, and we have no doubt that the Ministry of Health has been wise to ask the assistance of local authorities in securing accurate dispensing, especially in view of the fact that the Pharmaceutical Society has no disciplinary power to prevent an incompetent or culpable pharmacist from practising. We agree that it is not possible, nor is it necessary, to insist upon a high degree of percentual accuracy for every ingredient. Medicine bottles as at present manufactured differ considerably in content, the graduation cannot be accurate to the second place of decimals, the patient does not measure the dose with any great precision, and there is a wide margin in most cases between the therapeutic and the toxic dose. But the dispensing chemist before he receives his title has acquired an extensive knowledge of chemistry, including quantitative and qualitative analysis, after having passed a matriculation examination or its near equivalent. He is well qualified to know the value of precision and where it is imperative to be precise. The human factor necessarily enters largely into dispensing, which, as we know, is not a particularly remunerative part of the pharmacist's business. Nevertheless all good pharmacists do attain a practicable and reasonable degree of accuracy.

In respect of what is reasonably practicable the report recently submitted to the Public Health Committee of the county borough of Salford by its public analyst, Mr. G. D. ELSDON, is of special interest at the present moment. Three years ago, after conferring with the local pharmaceutical association, a workable scheme was devised of checking the practice of pharmacists by analysis of test mixtures. The scheme is roughly this. A prescription bearing the name and address of a panel patient is submitted by an unknown messenger to a panel pharmacist. The messenger having received the medicine calls the inspector into the shop, when the sample is then and there divided into three parts, one being left with the vendor, the second being delivered to the public analyst, and the third kept for reference in case of dispute. It was agreed between pharmacist and local authority that the strength of prescriptions should not differ by more than 10 per cent. from the truth, except in cases such as sodium bicarbonate, where a little more licence might be allowed, no hard-and-fast rule being laid down to cover every case. As a result of these analyses, the considerable laxity in dispensing at first found has shown great improvement; last year the proportion of gross error was only 5 per cent., compared with an average of over 20 per cent. in the years 1914 to 1918. Mr. ELSDON attributes this success to the friendly spirit which has existed among all the parties concerned. Pharmacists who were merely careless have become more careful, whilst the few who were really unfitted for their task by temperament or training are dropping out or are being removed from the panel. This result has been obtained without setting up an impossible standard and without harassing the pharmacist by administrative detail. It has been achieved without legal prosecutions or public scandal. Mr. ELSDON believes, and we agree with him, that a reasonable

scheme of checking combined with friendly coöperation between municipal officers and pharmacists would raise the standard of dispensing in other parts of the country to that now obtaining in Salford. There is no divergence of interest in the matter; pharmacists and doctors are alike concerned.

CRIME AND PUNISHMENT.

LAST week we dealt with insanity in relation to the criminal law, a problem recently brought into considerable prominence, and still waiting solution. But this question is only a part of the larger subject, crime and punishment, in which many thinking people are keenly interested. The number of books on prisons or prison reform published during the last year, the articles which recently appeared in the *Manchester Guardian*, and the public meetings to hear lectures or discussions, leave no doubt on this point. But just as in the matter of responsibility in relation to mental disease it is the lawyers and not the doctors who are the primary advocates of change, so in the larger problem it is doubtful whether the medical profession is taking the lead in insisting on more rational methods. It is true that two of the most important new books on crime have been written by Dr. M. HAMBLIN SMITH and Dr. MARY GORDON respectively, but the number of medical workers in this field is very limited. The meetings described are not usually organised or attended by medical practitioners, while the magistrates and others present sometimes complain of the lack of interest or understanding in their medical officer, or deplore the fact that no one is competent in their district to act as medical adviser to the Bench. It is idle to pretend that any qualified medical practitioner can do this; the student has no training in mental defect; his experience of insanity is insufficient to diagnose an incipient or difficult case, while psychology is practically a closed book.

How many medical practitioners, if asked, have any definite ideas or up-to-date knowledge as to whether treatment or punishment is the more hopeful method of dealing with crime? How many know what type of case is amenable to special treatment, still less what that treatment should be, or can say which are the unexplored fields most urgently demanding investigation? One of the correspondents to the above-mentioned newspaper stated that it would be greatly to the public advantage that 1000 consecutive unselected cases before the courts in Birmingham should be specially examined to determine what proportion of cases required such investigation, and incidentally to show how those requiring investigation could best be selected. Had this suggestion been made in regard to any other city than Birmingham or Bradford, always excepting London, would there be local psychological experts available? Such considerations led us to welcome the announcement in our advertisement columns of March 24th that a post-graduate medical course in crime and punishment would be again held at the Birmingham University in May. Although a fortnight's course is insufficient for training, it may be invaluable as a start to show the lines on which further experience should be sought. Those who would like to attend such a course, but hesitate under the impression that the systematic examination of delinquents is unlikely to become a matter of practical politics except in the remote future, would do well to note some of the circumstances that have led many to a fresh outlook on crime and prison life, and to consider how far they may be permanent. In the first place, the prison experiences in recent years of a large number of

educated and refined persons of both sexes, as conscientious objectors or suffragettes, have done much to enlighten public opinion. Many of these persons, no doubt, have recognised that prisons were not designed for such as they, and also that prisons may not affect ordinary delinquents in just the same way. Still, and at last, many realise that there are few on whom prison can be expected to have a good influence. Secondly, the advent of women into public life, and particularly their presence on the justices' bench, favours a new point of view. Feminine intuition has been quick to see that all is not well, and that radical changes are necessary. When those with such ideas look at the records available they find their worst suspicions confirmed; they learn that the majority of serious offenders have been convicted not once, but many times previously, and that nearly all habitual offenders begin their delinquent career at an early age. Lastly, but not least important, is the knowledge that where only doubt and uncertainty existed before, the new psychology has shed much light. Psychology is ultimately the science of human conduct. There is still much that is controversial, but one fact has been established—namely, that conduct is invariably the result of mental life; and all the causes which have been given as explanations of criminality are only operable in so far as they affect the offenders' mental life. This is the theme of Dr. HAMBLIN SMITH in his article in the last number of the *Howard Journal*, and more fully elaborated in his book "The Psychology of the Criminal." His ideas are confirmed in the January number of the *British Journal of Medical Psychology*, by Mr. CYRIL BURT, who shows that delinquency in the young is assignable to a number of factors, and that "psychological factors, whether due to heredity or environment, are supreme both in number and strength over all the rest." Dr. MARY GORDON insistently demands a psychological examination of offenders, while the plaint of less technical investigators is not that the handling of prisoners is unkind, but that it is non-understanding. Those who have studied the subject know that the proper examination of an offender is no light task. Mental defect and insanity must be excluded; a thorough physical examination is necessary, and in addition a searching psychological investigation.

The Birmingham scheme, for the recognition of those who in consequence of mental defect or other reason require treatment and not punishment, makes such an examination possible, alike for those remanded to prison or not in custody, when the justices consider it necessary. The annual reports show that of more than 450 cases remanded in prison for special examination less than 24 per cent. were subsequently sentenced to imprisonment, while of the smaller number remanded not in custody none were sent to prison, nearly all being placed under treatment rather than punished in any way. Such records prove the economy of the arrangement. They indicate that a larger number might be examined with advantage, particularly of less serious cases, many of whom will otherwise be serious cases at a later stage. Many of those placed on probation should be studied first and suitable conditions enacted in the order. The recommendation of some workers that delinquents should be studied not only in the courts and in prison, but also in the school or general psychological clinics, before they come under notice of the police at all, opens up other fields to the trained medical psychologist, who will not fail to realise that his work cannot be undertaken by the ordinary probation officer.

PAINTING AND LEAD POISONING.

THE story of the white lead controversy is a long one. It started in France, dating back over a hundred years to the time when, with the rise of modern industrialism, the custom was adopted of protecting surfaces with paint; in this country the plaster-front period of the Regency gave an impetus to the new fashion. Forthwith sprang up vested interests in the manufacture of the materials used and also complaints from the painters of sickness and deaths resulting therefrom. Meantime attention was diverted to lead poisoning occurring among makers of the white lead used and among potters where the same substance was used as a constituent of glaze; and powers were taken and enforced in this country under the Factory Acts for the protection of those employed. Investigation disclosed that lead poisoning resulted mainly from inhaling lead dust, and action taken to prevent such inhalation was followed by a splendid reduction of cases. Then, in 1911, committees were appointed to consider the use of lead materials in paints employed on buildings and on coaches and carriages; these committees examined the position carefully for over three years before issuing their reports. By this time France, in 1909, had passed a law, to come into force in 1914, prohibiting the use of white lead in paints, but the war intervened; in Belgium, Switzerland, Austria, and Germany regulations, more or less stringent on paper, had been adopted. But the results of these regulations were far from satisfactory, since plumbism among painters had hardly been brought below what was prevailing in this country. The House Painting Committee concluded—and the Geneva Convention, on Nov. 19th, 1921, has since reinforced the decision—that the use of lead in paints for internal painting should be prohibited. They also recommended its prohibition for external painting, although the position here was more difficult since other paints were less satisfactory; yet to permit the use of lead paints outside and prohibit them within seemed bound to create confusion and endless opportunities for evading regulations of prohibition. Moreover, there was evidence that with a demand non-lead paints capable of resisting the weather would soon appear; already in one instance, notwithstanding the suspension of most research due to the war, the expectation seems to have been fulfilled, for the Office of Works, after four years' tests, informed the Home Office in 1919 that, for priming coats of iron and steel work, several kinds of leadless paints had given satisfactory results. These results have naturally been severely criticised by the advocates of lead materials in paints. But the Coach Painting Committee, on finding that such concerns as the Daimler Motor Car Company, the Midland Railway, and the Bradford City Tramways had abandoned the use of lead paints with entirely satisfactory results, decided that others could follow these examples, and recommended prohibition of lead paints.

Just before the Geneva Conference was due last autumn to consider the matter, the British Government tied its hands by appointing a new departmental committee, on which the working painter was not represented. Nevertheless, the Geneva Conference agreed to a convention prohibiting lead paints for the internal painting of buildings after 1927, and instituting stringent regulations for the use of lead paints where not prohibited. The duty of the new Committee was clearly altered by this decision, and became that of determining how best the Geneva Convention could be carried out. To this aspect they seem to have turned their attention; and now,

after hearing 26 witnesses and meeting 13 times, they report.¹ They accept the Convention, but go even further in recommending the immediate prohibition of all dry rubbing down of painted surfaces. This process, on account of the dust generated, has long been accepted to be the main danger in the painting industry; but all practical witnesses before the 1911 committees stated that it could not be carried out damp. Recently, however, water-proof sandpaper has been introduced which permits damp rubbing down to be successfully adopted. The Committee then turn to the proposed regulations of the Convention for the house-painting trade, but can here see no hope of effective enforcement except through the goodwill and coöperation of the trade—i.e., except through inspection of the trade by the trade. When, however, the considered deliberations of the Committee are unhampered by the Convention, as in the matter of coach painting, they may be found to differ from the latter. Although as regards coach painting the Committee concluded that "there is a good deal more to be said for complete prohibition than in the case of house painting," and although what there was to be said was sufficient to lead them to accept prohibition for the internal painting of buildings, they "do not recommend prohibition" for coach-painting. Why?

INSTRUCTION IN MEDICAL PHYSICS.

WE publish in another column a letter from three of the examiners in physics for the triple qualification at Edinburgh, advocating the establishment in the medical curriculum of a definite course by a definite teacher of medical physics. We may anticipate at once the alternative views which the letter will produce. Some will be of the certain opinion that nothing in the nature of a further compulsory test should be added to the curriculum unless an equivalent in demand upon the student's time is subtracted. Others will suggest that the institution of such a compulsory course, if short and well-planned, though closed by a testing examination, would none the less assist rather than hinder the student, for comprehension of the principles of medical physics would bear fruit in most of the divisions of the medical curriculum. But all those who feel in this progressive way towards instruction in medical physics may not feel disposed to go so far as the letter from Dr. Alfred Daniell and his co-signatories, and undoubtedly the institution of another special examination would to-day be a confession of the failure of the existing course to meet its design. That design has been to examine the student at the beginning of his career in physics generally, leaving the special teachers in their turn to show him how the general information can be particularly applied. The demand for a definite course of medical physics at some later stage of the curriculum is a statement, in other words, that the teachers of the final subjects do not or cannot impart a knowledge of physics, in their medical application, so as to give the student a reason either for the pathological happenings which he is observing or the therapeutic technique which he is acquiring. Clearly honours physics cannot be taught to a medical student either before or during his curriculum; and if he is compelled to revise his knowledge at some point in the course the extent of that revision will always be a matter of dispute. The examiners in the final subjects could meet the situation, as it exists at present, by resolving to set in certain of the papers questions involving a knowledge of medical physics, but they would be loth to reject candidates whose inability to answer the questions might be due to absence of any facilities for acquiring the necessary knowledge.

¹ Report of Committee on Industrial Paints. H.M. Stationery Office, 1923. 2s. 6d.

Annotations.

"Ne quid nimis."

THE FUTURE OF MEDICAL BENEFIT.

IT has now been publicly announced that the Insurance Acts Committee of the British Medical Association is to meet the Ministry of Health on April 26th to discuss proposals in regard to the capitation fee for medical practice under the Insurance Acts. On May 12th the proposals of the Ministry and the opinion of the Insurance Acts Committee on these proposals will be circulated to the panel committees throughout the country; and on June 7th representatives of the panel committees are to meet, being fully instructed in the views and temper of their constituents. Dr. A. Cox reminded a meeting of practitioners a few days ago that this conference will not only be concerned with the amount of the capitation fee but also with the terms of service—that is to say, with the amount of professional time and effort which are to be given in exchange for payment. The position is not simply one of financial economy. When the Geddes Committee decided that the State purse was too impoverished to add its quota to that of employer and insured person in a national scheme of health insurance, the deficit was made up for the time being by accumulated funds at the disposal of approved societies; moneys, be it noted, which had been contributed by the three parties mentioned in excess of what was required at the time for medical and other benefits. Maybe the employer and the insured person consider that their present quota is sufficient. Maybe the National Exchequer is still unable to make its promised contribution. Nevertheless it is quite certain that a capitation fee must be paid which will obtain willing service from insurance practitioners, and it is also quite certain that some Government department must continue to control the incomings and outgoings under the Act. The Ministry of Health is in a position to assess the medical needs of insured persons and to allocate contributions equitably, and there is no doubt that the Ministry must remain as third party in any negotiations between the doctors and approved societies which these prefer not to arrange between themselves. As time goes on the duties of the chairman at this health conference, for this is what the position of the Ministry amounts to, will become less onerous. At the present time the chair remains. When settlement is reached insurance practice is entitled, in Dr. Cox's words, to a little blessed tranquillity, for no system on earth, least of all a complicated scheme of health insurance, can stand continual pulling up by the roots to see how it is getting on.

SCHOOL INTELLIGENCE AND HOME CONDITIONS.

THE question of the relative importance of heredity and environment in the upbringing of children is still unsettled, except in the minds of propagandists. A valuable contribution to the study of this question has just been published by the Medical Research Council, in the form of a report on "the relation between home conditions and the intelligence of school-children." Unfortunately, the study was interrupted by the death of Mrs. Frances Wood who collected the data, the material being tabulated and analysed by Dr. Isserlis. Mrs. Wood had intended to investigate the relation not only of home conditions, but also of physical health and hereditary parental abilities to the intelligence of children. Had all this been carried out with the same thoroughness and care that characterise the published report, it would have been no insignificant contribution to the solution of a problem with wide social, political, and economic implications. Nevertheless, as it stands, the report is a model for the study of these problems. The correlation between the school-child's intelligence and his environment

works out in Mrs. Wood's study at between 0.3 to 0.4, a lower figure, as Mr. Cyril Burt points out in a foreword, than has been obtained in previous work. By itself this only proves that improvement of home conditions may be expected to react upon the intelligence of the children, but the eugenicist may still contend that improvement of home conditions is largely dependent upon the hereditary qualities of the parents. It is much to be desired that the investigation should be pursued further on the lines originally intended.

HEAT PENETRATION.

Sol est remediorum maximum is a saying attributed to the elder Pliny, and no doubt sun treatment is as old as human culture, but its exact study is of recent date. An admirable chapter by Dr. A. Rosselet, lecturer on physiotherapy at Geneva University, on the scientific basis of heliotherapy is contained in Dr. A. Rollier's new book¹ on Heliotherapy, to which we shall return. Here we are concerned with the penetration of heat to the deeper tissues of the body. Dr. Rosselet regards it probable that the rise of temperature which takes place during sun-bathing, especially in well-acclimatised patients, is due in part to direct warming of the blood. In Finsen's Clinic at Copenhagen Dr. C. Sonne showed that luminous rays are far more effective in heating up the blood as it circulates in the skin than are the infra-red rays, and in this development of warmth he saw the principal physiological factor of sun treatment. It is generally agreed that the effect of direct sunlight exceeds in therapeutic potency that of any other variety of rays. The effect of light and heat rays on various tissues of the body has now been made the subject of close study at the National Institute for Medical Research, and in our present issue Dr. Leonard Hill and Dr. J. A. Campbell record some interesting results of experimental work, the temperature being determined by delicate thermo-electric couples mounted in hypodermic needles ingeniously designed by Dr. E. J. Schuster. The authors found that exposure of the whole body of a rabbit to the sun's rays at Hampstead rapidly increased the temperature of the deeper tissues; exposure of the head and upper part of the body alone was, on the contrary, followed by a fall of temperature. Local exposure of the head resulted in a definite increase of temperature of the scalp and brain. They came to the same conclusion as Sonne—namely, that the luminous rays actually heat up the subcutaneous tissues to a greater degree than do the non-luminous rays.

Another interesting study of heat penetration appears in the *Japan Medical World* for Feb. 15th, where Surgeon-Lieutenant N. Fukui records the effect produced by subjecting the testicle of a rabbit to the action of heat. He has found that heat produces very definite regressive changes in the seminiferous tubules, changes that are similar and just as intense as those effected by ligature of the vas or exposure to X rays. For the purpose of his experiments he employed sunlight, a powerful arc light, and warm water baths. Histological examination of the testicle after exposure to these agencies showed that selective destruction of the generative cells of the tubules had taken place, leaving the Sertoli cells and the interstitial cells of Leydig intact. Indeed, as after ligature of the vas, there would appear to have been some proliferation of the latter. A point of interest in the experiments is that a comparatively low temperature was sufficient to produce change; thus exposure of the scrotum of a rabbit to afternoon sunlight in summer, for a period of three hours, gave rise to the phenomenon termed by the writer "heat-testicle." Similarly a warm bath at 45° C., for the same period of time, produced identical changes. These observations, if confirmed, have a bearing on more than one problem in medicine. It is only within recent years that the importance of male sterility has been realised and the discovery that spermatogenesis is so sensitive to changes in the temperature of the testicles may throw light on

¹ Oxford Medical Publications, 1923. 25s.

otherwise inexplicable cases of azoospermia. Again, should the induction of regressive changes in the seminiferous tubules by exposure to heat prove to be effective in man, it would provide an alternative method of bringing about the artificial sterilisation of undesirable males. One of the objections raised to the enforced sterilisation of undesirables is the fact that up to the present an open operation is the only permanent method of achieving it. Exposure of the testicles to warmth or sunlight entails no risk or hardship to the subject, and should it be effective would afford a satisfactory solution to a difficult problem. It is, however, in the highest degree improbable that the regressive changes noted by Dr. Fukui are permanent and that lifelong sterility can be achieved by exposure of the testicles to such a low grade of heat for so short a period. Sterilisation by means of X rays, unless a particularly intense action on the testicle is achieved, is only temporary, and we should expect the same to hold for sterilisation by means of heat. The fact that Dr. Fukui has noted an increase in Leydig cells concurrently with regressive change in the tubules is of special interest at the present time when attention is being directed to Steinach's observations on the results of ligation of the vas. Dr. Fukui's work must be repeated and confirmed not only by experiments on other animals, but by observations on the human being before it is safe to make any deductions. If the degree of heat necessary for the degeneration of the seminiferous tubules is so slight it should be feasible to obtain evidence of diminished fertility in stokers, cooks, and Turkish-bath attendants, and thus to confirm or refute Dr. Fukui's laboratory observations on rabbits, dogs, cats, guinea-pigs, rats, and goats.

MUSCULAR DYSTROPHIES.

At the Devon and Exeter Medico-Chirurgical Society Dr. W. Gordon showed a case of pseudo-hypertrophic muscular paralysis, in which tenotomy for talipes equinus, performed by Mr. B. D. Dyball, had restored the ability to walk. Dr. Gordon pointed out how very greatly our conception of the muscular dystrophies had been simplified by accumulating knowledge of the rarer forms of disease. Formerly four varieties were separately described—the common pseudo-hypertrophic type and three much rarer varieties, atrophic from the onset—namely Erb's so-called "juvenile" type, Landouzy and Dejerine's "facio-scapulo-humeral" type, and Gowers's "distal" type. It was now known that, whereas the primarily atrophic varieties commonly occurred within affected families, sometimes one, sometimes another making appearance, pseudo-hypertrophy kept itself to itself. Hence it was sufficient for practical purposes to distinguish two types only of muscular dystrophy, the pseudo-hypertrophic and the primarily atrophic. Dr. Gordon laid stress on the following points of difference, eight in number:—

1st, and chief in respect of *prognosis*, the pseudo-hypertrophic died in nearly every case at or before puberty. The others commonly survived for many years.

2nd, and next in importance from the *diagnostic* standpoint, marked initial hypertrophy only occurred in the pseudo-hypertrophic.

3rd, regarding *treatment*, contractures were much more marked in the pseudo-hypertrophic.

4th, Pseudo-hypertrophics were generally diagnosable at 5 or 6 years of age; the others might begin at any age and generally at a much later one—for instance, Erb's misnamed "juvenile" type—usually first appeared between 15 and 35 but might begin in early childhood or in later life.

5th, Five out of six pseudo-hypertrophics were *boys*; the others were as often females as males.

6th, Pseudo-hypertrophics were much more apt to present *no history* of other cases in the family.

7th, Each type tended to *breed true*.

8th, The *muscles* most affected differed to a certain extent. Thus, although the lower parts of the great pectorals and the whole of the latissimi dorsi usually wasted much in both types, the pseudo-hypertrophics never had the face affected, although masseters and tongue rarely enlarged, whereas in the other type the face might suffer and, indeed, suffered first and characteristically in the Landouzy-

Dejerine variety. In pseudo-hypertrophics the trapezius rhomboids, or serratus were rarely affected, equally rarely the infraspinatus, supraspinatus, and deltoid in the other forms; while in pseudo-hypertrophics it was just these three muscles that were commonly and considerably enlarged.

In both types the diagnosis rested on three common features: The absence of fibrillation in the affected muscles, in contrast to the progressive muscular atrophies of spinal origin; the absence of all sensory changes; and the absence of reaction of degeneration. The case shown could be diagnosed at a glance, although only one group of muscles was pseudo-hypertrophic—viz., the calves. The coincident atrophy of the latissimi dorsi and of the lower fibres of the pectoralis major; the common history of difficulty of going upstairs; the obvious waddle; and the attempt to "climb up his own legs" when seated on the floor and told to get up—only frustrated by his pronounced club-feet—were sufficiently distinctive. Lifted by his armpits the boy simply slipped through the hands. To discover, said Dr. Gordon, pseudo-hypertrophic paralysis it was essential to look at the back. Only one muscular group was usually enlarged in front—namely, the thigh extensors; if hypertrophy was confined to one group of muscles, it was usually behind, the three commonest sites being the calves, the buttocks, and the infraspinati, the next commonest the supraspinati, deltoids, and triceps. Two muscles wasted primarily in all forms of the disease—namely, the latissimus dorsi and the lower part of the pectoralis major. Prognosis in pseudo-hypertrophic paralysis was unhappily of the worst—scarcely any case passed puberty; but it was well not to be too confident, for one patient was said to have survived to 40. Once bedridden, the downward course was greatly accelerated. Dr. Gordon concluded by calling attention to our lack of resource in muscular complaints generally, apart from so-called myalgias. Even in myositis the accepted remedies were not strikingly helpful. In muscular dystrophies, in myotonias, in amyotonia congenita of Oppenheim, and in myasthenia gravis medicine had hitherto to confess its impotence.

VETERINARY PRACTICE OF A BYGONE AGE.

THE second volume of Sir Frederick Smith's great History of Veterinary Literature in Britain During the Eighteenth Century is appearing in instalments as a supplement to the *Veterinary Journal*. In the first instalment the author notes that animal diseases were treated by two classes of practitioner, known as *farriers* and *cow-leeches*, both of whom borrowed their knowledge from writers on human anatomy and physiology. There was little original work or study of cause and effect, although certain individuals who came from among the ranks of the surgeons—e.g., Gibson, Osmer, and Taplin—built up good veterinary practices. In 1714 Thomas Bates, F.R.S., surgeon to H.M. household, dealt with an outbreak of cattle plague on lines differing little from those employed in cattle epidemics of the present day. But many of the books were written by laymen who were copyists. In 1730, however, William Burden, a captain of cavalry, endeavoured to convince the public that "the study of veterinary medicine and surgery is the work of an educated man and not the function of farriers, coachmen, and grooms." The influence of Solleysel, the French veterinarian, on much of the literature of the day was very noticeable. Henry Bracken, M.D., 1687–1764, to whom we owe the really enlightened books of the period—"Farriery Improved" and "The Traveller's Pocket Farrier"—himself the son of a Lancaster surgeon, although an unblushing plagiarist, brought in some clear reasoning of his own, and his treatment was simple, rational, and clean. He was also a firm believer in the prevention of disease, although he lived in a time when the liver of an eel, the flesh of the viper, the penis of a tortoise, and the moss from human skulls were stock therapeutic agents. Progress in animal medicine was necessarily very slow until the foundation of veterinary schools at the end of the century, first in France and

afterwards in this country. The lesson can clearly be drawn from Sir Frederick Smith's narrative that no real advance is possible in any branch of medical science without facilities for research into the causes of disease. The veterinarians of the eighteenth century were for the most part travelling round in a circle with no clear or intelligent guidance; their premises being false, their practice was devoid of useful result.

ASYLUM NURSING IN PARIS.

LAST November, after a preliminary study by Dr. A. Antheaume, the supervising committee of the Asiles de la Seine decided that in certain male wards of the Paris asylums the male attendants should be replaced by female nurses. The change, Dr. A. Rodiet tells us in a recent issue of *Le Progrès Médical*, is strenuously resisted by the attendants themselves, who take their stand on the ground that the morals of the nurses will be corrupted. Dr. Rodiet, who is himself in charge of the Ville-Evrard Asylum, points out that the experiment has been tried elsewhere, especially in Holland, where male attendants have disappeared, and that the experimental stage has been passed in more than one country. It is curious that he makes no reference to Britain, although at Morningside Prof. G. M. Robertson broke the first ground, and the authorities of Cardiff City Mental Hospital have carried the substitution of women for men to greater lengths than are contemplated in Paris. For the French proposal amounts to no more than to employ nurses for helpless and harmless patients who are confined to bed, general paralytics in the third stage, and congenital imbeciles or idiots. These limitations would certainly protect the nurse from offensive conduct on the part of patients. We must not overlook the advantage of a hospital atmosphere and the sympathetic care of women in cases where recovery is possible and capable of acceleration by congenial environment. It was with this object that the nursing of male patients by women was introduced in this country.

CHRONIC COWPERITIS.

Dr. Harry Cohen and Dr. Ralph L. Dourmashkin¹ of New York, who report an illustrative case, remark that in spite of the enormous quantity of literature on the various aspects of gonorrhoea, surprisingly little has been written on the subject of chronic infection of Cowper's glands as the underlying cause of recurrent attacks of chronic urethritis. The onset of acute cowperitis is ushered in by chills, rise of temperature, pain and tenderness in the perineum, and pain on defecation. The involvement is usually unilateral and is shown by redness, swelling, and induration in the perineum. Resolution takes place or the process goes on to suppuration, the abscess bursting either into the urethra or perineum and occasionally giving rise to a urinary fistula. The gonococci may remain in Cowper's glands for months or years and be the cause of reinfection of the urethra. The writers maintain that many cases of chronic urethritis attributed to prostatitis are really due to chronic cowperitis. The diagnosis of chronic cowperitis can be made by palpation of the inflamed gland, as in the case of chronic infection of the prostate or seminal vesicles. When Cowper's gland is enlarged it can be felt just anteriorly to the membranous urethra, which is in the middle line and at the lower margin of the prostate. Urethroscopy is also a valuable guide, as it shows the inflamed mouths of the ducts. Unlike its homologue Bartholin's gland, Cowper's gland is rarely infected by any other organism than the gonococcus. Tuberculosis of the gland, however, has been described by a few writers, so that in chronic cowperitis, with or without a fistula, a careful search should be made for tubercle bacilli. Treatment of chronic cowperitis consists in massaging the gland at regular intervals by inserting the index finger into the rectum and compressing the perineum with the thumb outside.

¹ Urologic and Cutaneous Review, March, 1923.

If massage is unsuccessful, excision of Cowper's gland is indicated, just as in the case of chronic gonorrhoea in the female where excision of Bartholin's gland has been advocated. In the case reported by the writers, in a man aged 28 suffering from chronic gonococcal urethritis, massage failed to produce any relief, but complete recovery rapidly took place after excision of an inflamed left Cowper's gland.

CONGENITAL ANOMALIES OF THE EYE.

IN another part of this issue Miss Ida C. Mann deals with a number of congenital anomalies of the eye which are liable to be confused with acquired conditions. It is important for the practitioner who takes any part at all in the treatment of eye diseases to be acquainted, not necessarily with every sort of anomaly which is liable to occur, but with those which may simulate the result of disease. A good example of this is the remains of pupillary membrane, a developmental structure which sometimes fails to be completely absorbed, leaving strands of tissue which are liable to be mistaken for synechiae resulting from acute iritis. The diagnosis should be easy with the help of a corneal loupe, but cases occur in which considerable care is required to determine whether the strands are attached to the margin or to the anterior surface of the iris. The most common congenital anomaly to be seen with the ophthalmoscope is caused by the persistence of the medullary sheath of the optic nerve fibres beyond the optic disc, where in normal cases it stops, causing white patches on the surface of the retina which to the uninitiated are liable to be mistaken for choroidal atrophy. In these and other cases, however, the question of treatment hardly arises, so that the results of a wrong diagnosis are not as a rule serious. Far different is it in certain cases where appearances due to congenital anomalies resemble what may be due to serious or even fatal disease. Here a little knowledge may be a dangerous thing. There is such a thing as pseudo-optic neuritis, a congenital condition; but he would be a bold man or woman who without a large experience in the examination of eyes should dismiss a disc with blurred margin after one examination as a case of this nature. If there is any suspicion of optic neuritis, the only safe rule is to keep the case under observation, at any rate, for a time. Similarly with congenitally large physiological cups, it is sometimes a matter of the greatest difficulty to distinguish them from glaucoma cups, and the result of examining the patient too hastily may be to lose valuable time in the diagnosis of an insidious disease. Other examples of possible disasters from a too hopeful diagnosis, given by Miss Mann, are the confusion of melanotic sarcoma with a subconjunctival mole, and the diagnosis of glioma as a persistent hyaloid artery.

PREVENTIVE INFANT FEEDING.

Prof. H. J. Gerstenberger, professor of pediatrics at Cleveland, Ohio, contributes to the March number of the *American Journal of Public Health* a practical résumé of our present knowledge of the means for prevention of nutritional disorders of infants and young children. Nutritional disorders in infants owe their occurrence to a variety of causes, such as hereditary factors, infections, bad housing, lack of sunlight, and inadequate diet, among which the most important, in Dr. Gerstenberger's view, undoubtedly is the last named. He adds that "those who state that infant feeding as it is practised even to-day in the big general way is successful are either blind, ignorant, or deceitful." His review of the percentage, or American, system of infant feeding is valuable historically, the results from the standpoint of general successful application having been small and disappointing; and he lays down the following as the qualifications needing to be fulfilled by an artificial food when the use of this cannot be avoided. The food must be complete if rickets and other nutritive disorders are to be avoided; the method of preparation must be

simple; the initial cost must be within the reach of the mass of consumers; it must be free from pathogenic germs; and it must "keep." Evidently a food which meets all the above requirements cannot be obtained in every home, and although success may be achieved in some instances by domestic methods, Dr. Gerstenberger arrives at the conclusion that "only one plan will work that will accomplish this purpose and at the same time be hygienic, economic, and practical as well, and that is the manufacture of such a product on a large scale and in a form that is handy for both parents and family physician." Such attempts have been made in the past, and they have not succeeded because (a) fat and mineral adaptation were not considered; (b) the importance of the regular addition to the diet of the anti-scorbutic vitamin was not recognised; and (c) the need of the anti-rachitic vitamin was unknown. Experience in Cleveland has shown that with the use of milk in dry or sterilised liquid form altogether satisfactory results can be obtained, given attention to the three points indicated above.

ALFRED HENRY FISON.

Dr. A. H. Fison, D.Sc. Lond., the secretary of the Gilchrist Educational Trust, who lost his life recently by an accident while fixing up a wireless aerial, was a very accomplished man and forceful personality, and his death is a real loss to the cause of scientific education. Born in 1857, he came of a family with old-fashioned Puritan ideals, which seem to have included a distrust of scientific knowledge and research. But in spite of his early environment—or, some may think, perhaps in consequence thereof—he adopted a scientific career, and became not only a lecturer with the rare gift of imparting his special information in an interesting manner to a general audience, but also a sound administrator and a teacher who earned the esteem of both pupils and colleagues. After graduating in science at the University of London he was appointed demonstrator under Prof. Carey Foster in University College. Here, later, he became assistant professor of physics in the College, and also staff lecturer in physics for the Oxford University Extension Delegacy. His appointment as lecturer in physics at Guy's Hospital dates from 1906, and the similar position which he held at the London Hospital Medical School, from 1910. The story of Dr. Fison's life is fully told in biographical notes published in the last issue of the *Guy's Hospital Gazette*.

THE TREATMENT OF SYPHILIS WITH BISMUTH.

IN the paper published on this subject by Dr. C. Levaditi in THE LANCET for March 31st it was stated that the first experimental tests of the toxicity of bismuth with a view to its exhibition in syphilis were carried out as long ago as 1889 by Balzer. Considering how remarkably effective this drug has recently proved itself in syphilis, it is strange that its usefulness in this respect should have been disregarded for so long. It is not as if bismuth were seldom given for other diseases; it has, for example, been extensively used for many years in the treatment of gastric ulcer and other diseases of the gastrointestinal tract, and the drug must often have been given for these diseases in persons also suffering from syphilis. Why, then, was its action on syphilis not noticed earlier? However, the impression which bismuth has made as an antisymphilitic remedy during the last few years on our French colleagues seems to have been very great. In a recent number of *Le Progrès Médical* Dr. M. H. Grenet has published details which form a useful supplement to Dr. Levaditi's paper. The preparations in use may be classified according as they are soluble or insoluble, and the indications for each are practically the same as for the soluble and insoluble preparations of mercury. An intramuscular injection of a soluble preparation of bismuth is the safest, for if toxic symptoms occur they can quickly be arrested by

discontinuing the injections. But if an intramuscular depôt of an insoluble preparation has been left, and toxic symptoms supervene, it is practically impossible to remove the depôt. On the other hand, such a depôt provides a more continuous and prolonged action of the drug, the injection of which need not often be repeated. Dr. Grenet makes it abundantly clear that bismuth is far from being a safe drug to inject. He does not give it by intravenous injection as recommended by certain of his colleagues, and he prefers the intramuscular route, partly on account of its greater simplicity. But even when given by intramuscular injection bismuth may give rise to stomatitis, hæmorrhagic enteritis, nephritis, and other complications. Indeed, as far as the kidneys are concerned, bismuth would seem to be more dangerous than mercury. On the other hand, though an excess of bismuth may injure the nervous system, the drug seems to be more effective than its two chief rivals in the treatment of syphilis of the nervous system. It is claimed for bismuth that it is particularly useful in cases which have proved arseno- and mercurio-resistant. But it is disappointing to read that bismuth has a less rapid effect on the Wassermann reaction than the arsenical preparations, and Dr. Grenet is wise in not claiming for bismuth a position of unquestioned pre-eminence among the antisymphilitic drugs. It may have a great future, but it has yet to stand the test of those late syphilitic diseases of the nervous system which have in the past so often mocked successful "cures."

THE OPEN PULMONARY TUBERCULOSIS OF OLD AGE.

THE tendency to regard the chronic bronchitis and emphysema of old age as a manifestation of active pulmonary tuberculosis seems to be growing. Many a case of infection in early childhood has, it is true, been traced to a bronchitic grandparent or a pensioned nurse with "asthmatic" proclivities. The literature of this subject is fairly bulky, and some of it reflects rather hardly on the aged as sources of contamination of the young. One of the most striking papers on this subject was published several years ago by Oppenheim and Le Coz, who performed necropsies on 330 old men, 60 of whom had died of tuberculosis. Among these 330 they found definite tuberculous lesions in 246, and in as many as 103 cases the tuberculous disease was still active. Thus they found active tuberculosis in 30 per cent. of their cases. In *La Presse Médicale* for March 24th Dr. P. Halbron and Dr. G. Potez have published observations which suggest that in being allotted the sinister rôle of tuberculosis carriers the aged may have often been maligned. The material examined consisted of about 1200 old men living in a "retreat." Among them there were 500 under medical treatment, and among these again 40 were selected for special examination. Certain of them had records of hæmoptyses and pleurisies, and there were signs of diffuse bronchitis, emphysema, and pleurisy. In as many as 21 of the 40 there were signs of apical lesions. In 15 out of 18 cases examined by the X rays signs indicative of tuberculous lesions were found. An exhaustive search was made for tubercle bacilli in the sputum, many sputum-positive cases being expected, but in none were tubercle bacilli found. This surprising result was confirmed by the findings in 21 necropsies. In as many as 17 there was, indeed, evidence of tuberculosis, but it was invariably arrested and inactive—never acute or even showing signs of chronic activity. The authors suggest that the comparatively sheltered life led by these old men may, at any rate partly, explain why their tuberculous lesions showed no activity, and it is possible that Oppenheim's and Le Coz's subjects showed such a high incidence of active tuberculosis because they were largely recruited from the most destitute classes. If this is the correct explanation of the remarkable difference in the two series it is a cogent argument in favour of taking

better care of the aged than is usually the case. Although the findings of Dr. Halbron and Dr. Potez are a useful sedative to scaremongers, it is obvious that a certain proportion of senile bronchitics and asthmatics must be disseminators of tubercle bacilli, and in justice to the non-tuberculous bronchitics it would be well if in every case of senile bronchitis the sputum were examined.

PRUSSIC ACID FUMIGATION.

A TRAGEDY at Chicago has recalled public attention to the dangers to human life of prussic acid fumigation. It appears that the owners of a basement restaurant, desiring to rid their premises of the attentions of the cockroach, entrusted the job to a man professionally engaged in the extermination of insect pests. This operator appears to have been at some pains to seal openings leading from the restaurant into the upper parts of the same building and to warn the other occupants to keep their windows open during the night. But an opening giving passage to a water-pipe was overlooked, with the result that the gas generated by the action of sulphuric acid on sodium cyanide escaped into a second-floor apartment to such purpose that six occupants lost their lives. There is no vestige of doubt that in prussic acid we are in possession of a handy and highly efficient vermin-killer, although its bactericidal action may be small. Unfortunately the gas is no respecter of persons, and we can only hope that the United States Government, which has insisted on the use, under proper safeguards, of hydrocyanic disinfection for ships arriving at American ports will also insist on its limitation in civilian communities to duly accredited officers. The amazing toxicity of the combination of one atom each of hydrogen, carbon, and nitrogen should preclude its use as a fumigant by anyone not directly responsible to the local sanitary authority. A few more such accidents as that which occurred in Chicago and the civilised world will refuse to have anything more to do with such a treacherous weapon.

THE CONTROL OF GOITRE IN MICHIGAN.

In a *Bulletin* issued from his department of health, the new Sanitary Commissioner for Chicago, Dr. Herman M. Bundesen, admits that goitre is on the increase in that city as well as along the shores of Lake Michigan and in the region of the Great Lakes in general. A survey of the public schools is now taking place in order to obtain exact information as to the extent of the affection amongst school-children, and a campaign of education amongst them will follow. Official goitre clinics are to be established throughout the city of Chicago. Dr. Bundesen himself thinks that the maximum of prevention coupled with the minimum of effort will be obtained by giving iodine continuously between the ages of 11 and 17 years. He quotes the result of two and a half years' treatment and observation amongst school-girls in Akron (Ohio), where some 2000 pupils were induced to take 2 g. of sodium iodide twice yearly. Among these only five individuals developed goitres, while among a similar number not taking prophylactic treatment nearly one-quarter showed thyroid enlargement. The conception of goitre as an iodine-deficiency disease is steadily gaining ground in the Western States of America, since it was found that in Portland (Oregon) and in Seattle and Tacoma (Washington) a rapid increase in goitre followed on an installation free from iodine brought from the Cascade Mountains.

We are informed that the British Drug Houses, Ltd., and Messrs. Allen and Hanburys, Ltd., working in conjunction, have overcome the technical difficulties of making insulin and are now prepared to supply it in moderate quantities. Their product is to be known as the A.B. brand. Although some thousands of doses have been made, the quantity available at present will not suffice to meet all requirements. Preference will therefore be given in supplying hospitals and medical men possessing facilities for pathological testing.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

XV.

THE TREATMENT OF INTESTINAL WORMS.

Tape-Worms.

THE secrets of success in the treatment of cases of tape-worm are (1) proper preparation of the patient, and (2) adequate dosage of the vermifuge. The patient should be kept on a liquid diet (1½ pints of milk and 1 of beef-tea) for 48 hours. During this period he should remain at rest, preferably in bed, and the bowels should be thoroughly cleared out by an efficient daily aperient—e.g., 5i. sulphate of soda t.d.s. Early on the morning of the third day he should be given a saline purge, and two hours afterwards the vermifuge should be administered. Liquid extract of male fern is usually employed, the dose being 1 drachm for a child and 1½ drachms for an adult. It may be given either in 15 capsules or as a draught made up with mist. amygdalæ co., and flavoured with a little oil of peppermint. If the capsules are used, one may be given every quarter of an hour until four or six have been taken. Two hours later a purge should be administered. Castor oil, though often employed, is not to be recommended for the purpose as some poisonous constituents of male fern are soluble in it. It is better to use black draught (mist. sennæ co.) or a seidlitz powder. If the bowels have not acted within an hour they should be emptied by an enema. The motions should be passed into a vessel containing warm water, and should be strained through black muslin to facilitate the search for the head.

Even when the above directions are carefully followed failure to get away the head will result in a good many instances. In that case there is nothing to be done but wait until segments reappear in the motions, and then to repeat the treatment. Other vermifuges are not likely to be more successful, but pelletierine tannate is worth a trial. It may be given after the usual preparation of the patient, in a dose of 8 gr., followed in two hours by 1 oz. of castor oil. It is not to be recommended for children below the age of 10.

Before the war I was in the habit of using the preparation known as filmaron with great success. It consists of the active principle of male fern dissolved in castor oil, the dose for an adult being ½ oz. or more. It is a German preparation, and is not now obtainable in this country. Chloroform and turpentine have also been used, but in the doses required are not devoid of risk. If chloroform is tried 1 drachm should be shaken up with 1 or 2 minims of croton oil, and given in half a tumblerful of milk whilst fasting. I have had no personal experience of this plan, but it has been highly spoken of.

Round Worms.

Santonin is an effective remedy for this form of parasite. The dose for an adult or a child of 12 years is 5 gr., and for a child of one year, 2 gr. It should be given in the morning on an empty stomach either as a powder, with the addition of ½ gr. calomel and 2 gr. of compound scammony powder, or in an emulsion containing ½ oz. castor oil. "Yellow vision" and redness of the urine may result, but are of no importance and disappear in 24 hours. As prophylactic measures all drinking water should be boiled, and raw vegetables avoided or thoroughly washed before consumption.

Thread-Worms.

The old-fashioned enemata are often effective if persistently used. The proper strength is 1 oz. of salt to the pint, and the injection should be repeated every other morning for a month. Infusion of quassia may be used instead, in a strength of 1 in 40 (which is stronger than the B.P. infusion), or the salt may be

added to the infusion. The injection should be given warm through a funnel and tube, the pelvis being raised. One and a half pints may be given to an adult, and 6 oz. or more to a young child.

A convenient local treatment is the use of suppositories containing $7\frac{1}{2}$ gr. of strong mercurial nitrate ointment. (In the case of children below the age of 4, a smaller suppository may be used.) One of these suppositories is inserted every other night. A little blue ointment inserted nightly into the rectum is perhaps as good. Amongst internal remedies santolin may be used in the same way as for round worms, or male fern as for tape-worm. Sulphur also is often effective in old-standing cases. It may be used either in the form of a morning dose of a sulphate water, or one or two sulphur lozenges may be given after each meal for prolonged periods. The writer has found it very useful in old-standing cases of thread-worms in adults.

Whatever treatment is adopted, it is important to take measures against re-infection. With this object the child should wear such sleeping garments as make access of the fingers to the anus impossible, and a little white precipitate ointment should be inserted into the anal canal and smeared round the orifice at bed-time. The same precautions should be taken, as regards diet, as in the case of round worms.

In all chronic and recurring cases the amount of starchy and sugary food should be cut down—patients have been cured by adopting a diabetic diet—and regular action of the bowels ensured either by the use of rhubarb and grey powder or of paraffin. There can be no doubt that the appendix often serves as a breeding ground for thread-worms and that the bowel can be constantly re-infected from it. In obstinate and old-standing cases in adults removal of the appendix has therefore been suggested in order to root out the parasites, but I am not aware that operation has ever actually been done solely with this object.

ROBERT HUTCHISON, M.D. Edin.,

Physician to the London Hospital and to the Hospital for Sick Children, Great Ormond-street.

Special Articles.

BODY HEAT AND EFFICIENCY.

THE fear of exposing the healthy body to cold, a tradition perpetuated by the popular nomenclature for infections of the nasal passages, should be finally extinguished by the results of the further observations with the kata-thermometer¹ just published. For too long hothouse conditions, suitable for the failing powers of the aged, for the injured in a state of shock, and for those suffering from chronic inflammations of the respiratory passages, have been regarded as equally suitable for the young and healthy. For fear of "catching cold" children were confined indoors in inclement weather, over-clothed, and at the same time exposed freely to massive infection in crowded places, while the need of abundant open-air exercise, to make them eat and metabolise their food, was neglected. The kata-thermometer was introduced by Dr. Leonard Hill, F.R.S., to measure the cooling and evaporative power of the environment of the skin and respiratory mucous membrane, since the suitability of atmospheric conditions for healthy individuals had been found to depend largely on properties not measurable by the ordinary thermometer.

In former green books (Nos. 32 and 52, Special Report Series, Medical Research Council) the results of earlier investigations were outlined, and the present volume represents the advance in the study of the kata-thermometer since their publication. Many new points have emerged. While it is not definitely estab-

lished that conditions condemned by the results of these studies do directly increase either morbidity or mortality, it is, at any rate, proved that atmospheric conditions, classified on the objective basis of kata-thermometric readings as unsatisfactory, are hard to endure; that in every case in which subjective sensations were controllable by objective test on industrial output, the test gave proof of diminished efficiency; and that the tempo of the fundamental metabolic processes of the body responds rapidly and considerably to changes of atmospheric condition. Certain interesting side issues have arisen. The desirability of habitual exposure of the young to cool atmospheric conditions is proved positively by the wonderful vigour of children undergoing open-air treatment, and negatively by the reluctance of those long accustomed to high temperatures and deficient cooling power to use the means provided for their mitigation. For example, potters, who start work at the age of 14, get so acclimatised to high temperature that they feel uncomfortable without it and do not take full advantage of the windows provided. Acclimatisation certainly increases the difficulties of applying the results of kata-thermometric readings to industrial conditions, but it is now established that mostly the worker's comfort as well as his efficiency is greatly increased by adequate air movement. The selection of an exact index of comfort has been found difficult. Under certain conditions, as when men are working naked in deep mines, the wet kata-thermometer affords a very exact index. When clothes are worn, however, the close comparison no longer holds. If it is known that the air temperature is a reasonable one the dry kata cooling power may be accepted as a fair index of comfort. This must be read in conjunction with the wet bulb reading and the dew point. We have not at the present time sufficient information to show what amount of air movement is desirable at various levels of wet bulb temperature, but it is gradually being collected in different industries.

Atmospheric Conditions in the Workshops.

The adequate investigation of the atmospheric conditions in a workshop is a laborious process. Observations have to be made at various times, seasons, and places. Again, the nature of certain industrial processes requires special atmospheric conditions, whereas in others no relaxation of normal standards need be required. Among the industries in the latter group investigated, in boot and shoe factories conditions were found to be fairly satisfactory, in printing works much less so. In the former group are certain textile processes where a hot and humid atmosphere, essential to the maintenance of the quality and quantity of the material woven, causes much discomfort to weavers in summer. Here, by the use of suitable ventilating fans, or an ingenious method of attaining the same end—attaching strips of material to the moving heald roller of the loom, the movement of air in the vicinity of the worker, and consequently his comfort, may be greatly increased. A comparison of conditions in several laundries led to the belief that in many cases the temperature could be lowered and the ventilation improved to the relief of the employees; while in potters' shops the workers themselves will have to be educated to take advantage of the ventilation provided before more can be fairly demanded.

General Studies.

We have commented mainly on the industrial aspect of the work, recorded by Dr. H. M. Vernon, but actually only a small part of the physiological investigations detailed in this report is concerned therewith. Other sections include a technical study of the kata-thermometer as a physical instrument by Miss D. Hargood Ash and Dr. Hill; a comparison of kata-thermometer readings in temperate, alpine, and subtropical climates, with a note on the effect of increasing or lessening the humidity of the air in a room by Dr. Hill; kata-thermometric comparisons of methods of heating and ventilation by Mr. T. Bedford and Mr. T. C. Angus; ventilation tests on board a

¹ The Kata-thermometer in Studies of Body Heat and Efficiency. Medical Research Council, Special Report Series No. 73. H.M. Stationery Office. 1923. Pp. 196. 5s.

large Atlantic liner by Mr. Angus; and observations on metabolism during rest and work, with special reference to atmospheric cooling power, by Dr. Hill, in collaboration with Dr. J. Argyll Campbell. In this section is a note on the preservation of life in shipwrecked persons, which may be of great practical importance. It is proposed to substitute rafts for boats on ships, as rafts can be piled on deck in larger numbers. The provision of concentrated food or drink in the lockers is regarded as of little importance compared with the problem of preserving body heat. The conclusions reached from experimental drenching of a most self-sacrificing volunteer is that the complete covering even of wet clothes by thin mackintosh suits, which could be stored in the lockers, would afford great protection and thus contribute largely to the preservation of life in survivors of the wreck.

Three appendices by Dr. G. H. J. Schuster, Miss May Smith, and Mr. Angus conclude a report which, with its predecessors, will long remain the reference for those undertaking investigations of atmospheric conditions.

The observations summarised in these reports are sufficient to indicate the value of kata-thermometer readings in factories, workshops, and on board ships, where incidentally the use of heated air for purposes of cabin ventilation is likely to be superseded in the future by fresh air combined with direct heating, radiators being employed where required. Even a considerable outlay in installing better systems of ventilation would repay itself in many shops and ships, and it is evident that further controlled systematic investigations on the pattern provided will lead to valuable results.

MEDICINE AND THE LAW.

MARRIAGE AND PROFESSIONAL CONFIDENCE.

A CORRESPONDENT inquires how far a medical man is "right in telling a wife what is the matter with her husband, if she asks," and states the case which prompted the question. The husband had contracted syphilis many years before his marriage, and there was no evidence that he had ever infected his wife. His symptoms pointed to some affection of the nervous system, the actual cause and name of which the wife demanded to be told, refusing to be put off with any evasion of her inquiries. What should she be told? There is a good deal of difference here from the usual difficult position summarised by Dr. Amand Routh in an article on "Syphilis and Marriage" in THE LANCET of March 31st. Here Dr. Routh was referring to the position of a medical man desirous of preventing the marriage of a syphilitic patient, male or female, who refuses to desist from his intention in response to advice. He pointed out that to warn the parents of the other contracting party, or that other party, himself or herself, might not only be regarded as a breach of confidence, but might form the subject of an action for defamation. The latter risk, we suggest, should be disregarded as trifling, for no judge or jury would be the least likely to treat such a communication as anything but privileged, if the medical man failed to prove it true in substance and fact, but could show also that he had not made the allegation rashly. Of the question of professional secrecy the same certain language cannot be used: opinions differ as to the medical man's duty, and every practitioner must therefore bear the responsibility of his action. No one can fall back upon an inviolable rule, and there is no law of the State enjoining professional secrecy. The patient's secret should be rigorously kept subject to conditions sometimes affecting particular cases, and the difference between the situation of the person already married who has not contaminated the partner, and that of the person proposing to marry who may contaminate the partner, is obvious.

This is held to be the ethical attitude of the medical profession. It is not required that a medical man should go to prison for disobeying a judge's order to

give evidence in the interest of justice, and there must be occasions and conditions when the most scrupulous professional conscience would acquiesce in the departure from principle. Such occasions and conditions are of infinite variety, and occur not only with regard to venereal disease, but as to what may be called "guilty secrets" generally; and not only with reference to possible revelation to a husband or a wife, but with reference also to revelation to other relatives, such as parents, or to strangers. Again, information may be sought from the doctor, or circumstances may suggest that he ought to give it unasked. The imaginable conditions are so varied that it has been found only possible to suggest a general principle of guidance. The patient's interests, physical or otherwise, must be the first consideration of the medical adviser, who must upon some occasions weigh against these the interests, physical or otherwise, of other persons.

In the particular question referred to us by our correspondent, it is not clear whether the patient would suffer or gain in respect of his health and treatment, or in other respects, by his wife being informed as to the cause of his illness; nor is it clear whether or not the husband might with advantage be induced to inform her himself. Upon the facts as stated it hardly seems that the wife would have any right to know more than her husband chose to tell her. The medical man has every right to protest, where he can do so, against being made a conspirator.

A DANGEROUS IMPOSTOR.

A man, who had signed his name to a bogus medical certificate as R. Cunningham Strachan, M.B., Ch.M. Edin., without having any such qualifications, was fined recently at the West London police-court £10, with the alternative of 28 days' imprisonment. He got off lightly, for the certificate which he signed was to enable a teacher to absent herself from her duties, as suffering from gastric catarrh, whereas in fact she was resorting to the house of a woman, named Maude Olive Beaumont, in order to have an illegal operation performed. It is true that there was no evidence that Strachan knew there was to be such an operation, or indeed that he even saw the girl, but she afterwards died owing to the operation, and Beaumont was sentenced to seven years' penal servitude at the Old Bailey, a sentence richly deserved. It is perfectly evident that Strachan must have known that the certificate would be used for some wrong purpose, whether he knew what that purpose was or not, and the danger to the public is considerable if certificates purporting to be issued by medical men can be given by any fraudulent person with comparative impunity. There was another person concerned with the death of the girl, who got off scot-free—namely, the man who introduced her to the abortionist, and who had had recourse to the same woman before; unfortunately his evidence was necessary in order to obtain her conviction.

INFANT INSURANCE.

An important case has come before the Shoreham Petty Sessional Justices. It was a prosecution under the Friendly Societies Act of 1896, Herbert Ward, an insurance agent, and H. M. Mackintosh, the Hove branch manager of the Pearl Assurance Company, being summoned for paying money on the death of a child under 5, which, added to other amounts payable, exceeded £6. There was also a summons against the defendants for paying money on the death of a child without inquiring what other amount had been paid. Mr. A. J. R. Haggard, for the Registrar of Friendly Societies, pointed out to the justices that a very important principle was involved in this question of child insurance. The Act was passed to prevent traffic in insurance of infant life and also to remove the bad moral effect caused by allowing parents to profit by the death of their children. There was no suggestion in these proceedings that any of those abuses had been practised. The Company had done its best at all times to ensure that the sections of the Act should be observed, and the Registrar of the Friendly

Societies was confident that the Company on realising that a mistake had been made had been zealous in trying to remedy it. Yet the Registrar, in view of the importance of the principle involved, felt he must take some action. The child was insured in three societies. Ward, the Pearl agent, made a payment of £3 15s., but it was subsequently ascertained that this amount, with other sums payable by the other societies, brought the amount payable to just over the £6 maximum. Mr. H. E. Trangmar, on behalf of Ward and Mackintosh, pleaded guilty to a highly technical offence, which had been inadvertently committed; and Mr. Graham Hooper, for the Pearl Assurance Company, pointed out that it was through the immediate action of his clients that the matter was brought to light. Directly they knew of the fact they took steps for the matter to be brought to the notice of the Registrar. The Chairman of the Bench (Mr. W. A. Hounson) said the justices regarded the case as one having been brought forward in the public interest. It was of the first moment because it was evident that long years of consideration and very considerable legislation had taken place in order that abuses of this sort might be prevented. In the particular case only a small amount (5s.) was at issue, and the facts showed that the legislation had produced a very good effect, inasmuch as this was a very exceptional case. There would be no conviction, but the court costs (16s.) would have to be paid, while the application for £5 5s. expenses was perfectly legitimate and must be paid.

WHOLESALE SMUGGLING OF DANGEROUS DRUGS.

A man named Humphrey pleaded guilty recently at the Guildhall Police Court to a charge of unlawfully offering to procure morphine, heroin, and cocaine for the Tong Say Company, of Amoy, China, contrary to R. 3 of the Dangerous Drugs Regulations of May 20th, 1921. The transaction upon which the charge was based was not a solitary attempt to procure drugs, for the accused had previously almost carried through at least one deal of considerable magnitude, and his proceedings, as described by counsel, proved, if it were necessary to prove it, that only energetic and effective control, with the coöperation of all countries where abuses may take place, can check the trade in dangerous drugs—or, indeed, render it anything but an attractive business for unscrupulous and ingenious persons. Humphrey combined a hardware business in the City with the secret shipping of opium products in large quantities, and in sending the peccant stuff to China, was introducing it into a country in the teeth of prohibition by the Government. He was sentenced to the maximum penalty now provided, a fine of £200 and six months' imprisonment in the second division, or three months more in default of the payment of his fine.

His case supplies an authentic record of facts pointing to the necessity for heavier penalties being made possible in such cases, for the particulars disclosed proved the magnitude and the profits of trade. The conviction of Humphrey should show his fellows that the vigilance of the police, in spite of obvious difficulties in their way, cannot always be evaded, but the punishment may not deter persons from taking the risk. The goods forwarded by Humphrey were obtained from dealers in France, of which the French Government will presumably take cognisance. Somehow the police in China had information of a shipment which led to the arrest on board ship at Hong-Kong of a Japanese named Tieuw, who in due course received a sentence of imprisonment. Under his control there were found cases which contained certain furniture, two sofas and four armchairs, in the upholstery of which were concealed 2500 oz. of cocaine and 2400 oz. of morphine, estimated by counsel as representing 4,375,000 and 2,100,000 doses respectively. In England intercepted correspondence to and from Humphrey expressed the regret of both parties for the misfortune of Tieuw, knowledge that their documents had been seized, and of the consequent necessity for a new code, and the willingness

of Humphrey to conduct fresh business. He offered to procure and ship a quantity of cocaine, said to be equivalent to 87,500,000 doses, which he suggested could be sold in China at 48s. per oz. to realise an estimated profit of £79,000, with a possibility of sale at a price as high as 200s. per oz. In an early contract quoted Tong Say had agreed to purchase from Humphrey not less than 1000 lb. per annum. It is not to be wondered that the Chinese Government is anxious to stop such a trade or that persons can be found to conduct such illicit retail.

The police of both countries are to be congratulated upon the capture of Humphrey, but the suppression of such traffic must depend upon the deterrence of unscrupulous individuals by heavier penalties, and upon the activity of the Government of the countries where manufacture takes place.

TUBERCULOSIS.

The Late Results of Sanatorium Treatment.

Prof. F. Reiche,¹ chief of the General Hamburg-Barmbeck Hospital, has lately published statistics showing the results of sanatorium treatment 17 years or more after discharge. The patients belonged to the insured class, and, thanks to the coöperation of the insurance officials, Prof. Reiche was able to trace most of his old patients, in spite of the length of the interval since their discharge. There were 1866 patients given sanatorium treatment for pulmonary tuberculosis in the period 1895–1904. It was found that in 1921—i.e., after an average interval of 22 years—46.9 per cent. were still perfectly fit for work, 18.2 per cent. were invalids, and 35.2 per cent. were dead. Many of the deaths were due to causes other than tuberculosis. All the patients were examined by Prof. Reiche in person, and he is sure that only very few could have been swept into the sanatorium net without being tuberculous. But quite a half of the total number of cases represented slight and early forms of the disease, and in as great a proportion as 24 per cent. two courses of sanatorium treatment were given, and in 7 per cent. three such courses were given. With these encouraging statistics for his text, Prof. Reiche urges the importance of institutional treatment for the tuberculous.

New York's 1922 Tuberculosis Death-rate.

New York has again established a record for a low tuberculosis death-rate. In 1922 this death-rate was 99 per 100,000 inhabitants, and never before has it been below 100. In 1921 it was 103. In 1910 tuberculosis caused 13 per cent. of all the deaths in New York; in 1922 this figure was reduced to 8 per cent. In the *Bulletin* for January and February, 1923, of the New York Tuberculosis Association, in which these figures are given, the future of the tuberculosis campaign is discussed. Although the tuberculosis death-rate has been reduced in New York by 53 per cent. since 1910, the falling curve now shows a tendency to flatten out, and there are still more than 25,000 sufferers from tuberculosis in the city. In addition to the measures already in force, three others are advocated as a means to giving "a death-blow to tuberculosis." They are: (1) Pasteurisation not only of milk but of all dairy products such as cream (including ice-cream), butter, and cheese; (2) extension of the system of "nutrition classes" to all children found under-nourished in the schools; (3) the establishment of industrial health services by anti-tuberculosis institutions, especially dispensaries, and by other health agencies.

The Unreliability of a Single Pirquet Test.

To show how misleading a single Pirquet test may be in childhood, Dr. O. Wiese² has published the results of the tuberculin examination of 800 children between the ages 5 and 15, by his assistant, Dr. H.

¹ Beitr. z. Klin. d. Tuberk., 1923, liv., 210.

² Ibid., 1922, liii., 470.

Rennebaum. A positive reaction to the first Pirquet test with old tuberculin was obtained in 537 cases. Of the remaining 263 cases which gave a negative reaction, as many as 170, or 64.6 per cent., were induced to give a positive reaction by repeating the Pirquet test with old tuberculin, by substituting Höchst cuti-tuberculin or Merck's diagnostic tuberculin for old tuberculin, by combining old tuberculin with "perlsucht" tuberculin, or by giving intracutaneous injections of old tuberculin in various strengths. It is thus evident that a single Pirquet test is of comparatively little value if it is negative.

Fashions in the Diagnosis and Treatment of Tuberculosis.

A combined report,³ dealing with the activities of 34 German hospitals in 1921, is an instructive mirror of the changes taking place in the attitude of the German medical profession both towards diagnosis and treatment. With regard to diagnosis, the fashion at present is to label almost every child of weakly constitution as a case of bronchial gland tuberculosis. A few years ago the diagnosis would have been anæmia, and it is perhaps an advance that this loosely formulated diagnosis is beginning to drop out of fashion. With regard to fashions in treatment, heliotherapy appears to have been practised only in 2 to 3 per cent. of all the cases of pulmonary tuberculosis. But the quartz-mercury lamp was used in 19 per cent. of the male patients and 21 per cent. of the female patients. Tuberculin probably enjoys greater popularity in Germany than in this country, and about 20 per cent. of the sanatorium patients were given some form of tuberculin treatment. The cutaneous and percutaneous routes are the most popular at present, and Ponndorf's and Petruschky's methods of giving tuberculin through the skin appear to be extensively adopted in general practice, as well as in institutions in Germany. As many as 12 of the 34 institutions had not practised artificial pneumothorax treatment in the year under review, and only about 7 per cent. of the patients in the second and third stages of the disease had been given this treatment. There were, however, certain sanatoriums in which up to 15 per cent. of the second- and third-stage patients were given lung collapse treatment. This practice of issuing a combined report of a large group of sanatoriums is one that might well be followed in this country; pooling knowledge and experience has a stimulating as well as a corrective effect.

ROUMANIA.

(FROM OUR OWN CORRESPONDENT.)

Congress of Physicians in Bucharest.

At the recent Congress of Rumanian Physicians, held in Bucharest, Prof. Jacobovici delivered an introductory address, in which he stated that the status of the medical practitioner was at present depressed to that of the artisan. Hence, he said, arose struggles for appointments, demands for a medical strike. Some medical men had been smitten with the desire of gain; an element of industrialism had entered certain curative institutions and sanatoriums owned by doctors, who united the functions of medical directors and hotel proprietors, their aim being insufficiently distinct. The whole range of medicine could not now be covered by one individual; the pathology and treatment of tuberculosis, of heart, intestinal and infectious diseases, of diseases of tissue change, and especially of nervous diseases, tended to become specialised. The delegation of nervous diseases to special departments was inevitable, but care must be taken to keep the latter in close touch with internal medicine.

Child-Suicide.

Dr. Bálint, of Sibin, has published a record relating to 200 cases of child-suicide in Europe; he notes that 50 cases were collected by Ferriani,

³ Ibid., 1922, liii., 459.

49 by Siegert, and 42 by Deutsch, of Budapest. The various causes are classified as predisposing, exciting, and general; the most striking fact that emerges is that the children who destroy themselves are generally nearing the close of school-life. The stress of examinations appears to be the most important single cause, whilst punishment, or the fear of it, poverty, and unhappiness of the parents, all contribute a part. Children who commit suicide are seldom, or never, normal, but many of them are intelligent and well-disposed, with a fair prospect of usefulness in life. The chosen form of death differs in various countries; in Germany, for instance, drowning is most frequently selected; in Hungary poison is the commonest means of self-destruction.

"Pathological Delirium."

The following case was lately described in the *Erdévi Orvosok Lapja* (Transylvanian Medical Weekly): A landowner at Bistritz was accused of attempting to murder a servant by firing at him with a revolver in the course of a quarrel. Defendant's counsel pleaded that the prisoner was not responsible for his act, as he had been drinking, and as a doctor had declared him to be suffering from "pathological delirium," in consequence of free indulgence in intoxicants. The prisoner was acquitted. A legal paper has condemned the judge's attitude, arguing that were a drunken man held not to be criminally responsible many crimes would frequently go unpunished, including murder and other serious offences against the person.

March 19th.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Health Reform and Dail Earann: A Congress of Teachers.

AN important debate took place at the annual congress of the Irish National Teachers last week, when, by invitation of the congress, Sir James Craig, M.P., ex-President of the Royal College of Physicians, gave an address on the medical inspection of schools. An Act was passed in 1919 at Westminster making compulsory in Ireland the medical inspection of school-children, and regulations for the carrying out of the Act were adopted by the Local Government Board and approved by the Board of National Education. The Act, however, has only now been put in force, and the public requires education as to the necessity for it. Sir James Craig made an excellent case, and obtained the full sympathy of the national teachers, a body whose goodwill is essential for the successful carrying out of any system of school inspection. He also took the opportunity of pressing forward the demand for the establishment of a Ministry of Health in the Free State.

The debate following the address was of good service, as it showed that the teachers were fully awake to the importance of safeguarding the health of the young. The speech of Mr. Thomas Johnson, leader of the Labour party in Dail Earann, was specially important as laying down a definite health policy for his party. He said that the public required to be trained to these ideas, and should be told on every occasion, whether asking for national or local funds, what the country could afford, as the cost was going to be a very serious question. But the true wealth of the nation was to be found in the men and women of the nation, and here was a chance for a good investment. They must not economise in public health or in education, and he was glad that Sir James Craig had emphasised the necessity for a Ministry of Health, where he would certainly be supported by every member of the Labour party. The medical profession were, he added, much further ahead than the public, and they could safely follow the profession in their teaching.

The Ministry of Local Government has now made a statement, through a representative, to the *Freeman's Journal*, in which the sympathy of the

Ministry is avowed. "Practically all the matters referred to," said the representative of the Ministry, "are being examined by our experts, and the Ministry have taken steps to acquaint themselves fully with the conditions of legislation on health matters on the Continent and America . . . As regards the question of the central authority, it may be observed that the Ministry of Local Government at present included all the important functions of the Ministry of Health in England." The latter statement is erroneous, for the National Health Insurance Commission is not under the Ministry of Local Government, but in the department of the Minister for Finance.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

It is announced that Surg. Rear-Admiral Alexander Maclean, D.S.O., will succeed Surg. Rear-Admiral William Bett, C.B., in the medical charge of the Royal Naval Hospital, Haslar.

ROYAL ARMY MEDICAL CORPS.

Maj. T. C. Lucas, half pay list, late R.A.M.C., is placed on ret. pay on account of ill-health contracted on active service.

Capt. C. J. H. Little to be temp. Maj. whilst empld. as Dep. Asst. Dir. of Pathology.

Capt. A. A. B. Scott retires, receiving a gratuity.

TERRITORIAL ARMY.

Maj. J. C. Burton, having attained the age limit, is retired, and retains the rank of Maj.

The undermentioned relinquish their comms. and retain their rank: Capt. J. T. Samuel, E. W. Griffith, W. Alexander, A. F. B. Shaw, and O. C. O'Sullivan.

Capt. D. A. R. Haddon and J. E. G. Thomson resign their comms. and are granted the rank of Maj.

Lt. E. H. Ponder (late R.A.M.C., D. Force) to be Lt.

Second Lt. J. Smart (late The Cameronians) to be Lt.

General Hospitals: The undermentioned, having attained the age limit, are retired, and retain their rank except where otherwise stated: Lt.-Cols. J. Barlow and G. S. Middleton; Maj. R. H. Parry, J. H. Pringle, T. K. Monro, J. G. Andrew, J. B. McK. Anderson, J. K. Love, W. MacLennan, and H. Walker; Capt. D. Lamb, J. R. Riddell, R. S. Fullarton and J. Patrick (all granted the rank of Major); Capt. J. Hamilton, A. N. McGregor, A. B. Kelly, A. S. Tindal, D. W. Russell, J. Maclean, F. Macrae, E. Mackay, J. A. C. Macewan, J. D. Holmes, A. Fraser, D. Fyfe, J. G. Tomkinson, J. H. Martin, J. Laurie, R. B. Ness, J. McC. Johnston, J. Carslaw, J. Towart, J. Morton, A. A. Young, W. W. Christie, A. McLennan, E. G. Fortune, J. Gilchrist, A. H. Edwards, M. L. Taylor, J. Gracie, D. Watson, and C. Kerr (granted the rank of Maj.).

Supernumerary for Service with the O.T.C.: Lt. E. J. T. Thompson (late H.L.I.) to be Lt. for service with the Medical Unit of the Glasgow University Contingent, O.T.C.

TERRITORIAL ARMY RESERVE.

Capt. J. H. Wilkinson, having attained the age limit, is retired and retains the rank of Capt.

Capt. J. Browne, from General List, to be Maj.

Capt. E. D. Richards, from General List, to be Capt.

DEATHS IN THE SERVICES.

Inspector-General William Harris Lloyd, R.N., whose death on April 2nd, at the age of 87, we announced in these columns last week, was the oldest officer of his rank in the navy. Born in 1836, he qualified with the M.D. St. Andrews and the L.R.C.P.I. in 1856 and immediately joined the navy as a surgeon. He first saw service in the *Calcutta*, in which ship he took part in the China War during 1857-58, and was awarded the medal with clasps for Canton and Taku. In 1862, when serving with the flagship *Nile* in North America, he took charge of some yellow fever cases which had occurred in the screw sloop *Rinaldo*, and later became a staff surgeon. In 1866 he was appointed to the *Jason* in American waters. In 1870 he was appointed for special duty at Haslar, afterwards to Lisbon Hospital, and later to the Admiralty. In 1884 he was made Deputy Inspector-General of Hospitals and Fleets. At the International Congress of Medicine in London in 1881 he was secretary of the section of military surgeons, and in 1887 represented the Admiralty at the International Medical Congress at Washington. From 1888 to 1890 he was senior medical officer of the naval hospital at Hong-Kong, and from 1892 to 1895, with the rank of Inspector-General, he was senior medical officer at Plymouth Hospital. He was appointed honorary surgeon to Queen Victoria in

1894, an office which he has held under the succeeding sovereigns, and retired from active service in 1896. Inspector-General Lloyd married in 1870 Phoebe, a daughter of Lieutenant-General Vincent of the Bengal Army, by whom he had two daughters.

Correspondence.

"Audi alteram partem."

INTERNATIONAL PUBLIC HEALTH.

To the Editor of THE LANCET.

SIR,—The Second International Interchange of Public Health Officers, held under the auspices of the Health Section of the League of Nations and organised by the Society of Medical Officers of Health, having completed its course in Great Britain on April 10th, the visiting health officers are proceeding to Austria and Switzerland for further studies.

At the moment of departure the foreign delegates to this interchange are happy to avail themselves of the columns of THE LANCET in which to voice some expression of their appreciation of the magnificent opportunities for study which have been placed at their disposal, and of the courtesy with which all arrangements have been carried out. This is not the time to present a critical analysis of the current health practice of England in detail. That will come when the delegates, after careful study of the extensive reports and documents with which they have been furnished, and a resurvey of their own notes in perspective, are in a position to hand in their reports to their respective governments. But at the present time the outlines of the composition are before them, and a sufficiently impressive picture it makes. What the visitors intend to refer to at present is not the public health system of Great Britain, but rather to the course of study which they have enjoyed the privilege of taking here. On this subject they are of one opinion, that it was wisely planned, and has been carried out in the most efficient and graceful manner, so as to set a standard for future interchanges of this nature which it will be difficult to maintain, and perhaps impossible to surpass.

The delegates feel that it will be impossible for them to thank by name the hundreds of officials who have contributed with unfailing courtesy and patience to their instruction and comfort, or even to mention the various government departments which have planned and contributed to the programme, or the voluntary organisations which have joined with the rest in their entertainment. Let us say to all of these earnest, public-spirited men and women, who spend their lives in the service of humanity, that they have given us freely of their best, that they have instructed our minds and have touched our hearts, and that we are grateful. The task remains to us to turn to the best account the effort which has been expended here in behalf of human welfare.

We are, Sir, yours faithfully,

MEDICAL PHYSICS.

To the Editor of THE LANCET.

SIR,—We desire to bring before your readers our views regarding the teaching of medical physics in the later years of the curriculum. We understand that it is suggested in Edinburgh that the student might obtain some teaching of medical physics from the physiologist, some from the ophthalmologist, some from the laryngologist, &c., but we are of opinion that unless a definite course by a definite teacher, who is qualified to teach medical physics, is attended, and unless this is followed by a definite examination ad hoc, the subject would not receive the study and attention which it deserves. The information would be patchy, important points would inevitably be omitted, and the instruction would lack the consecutive and coherent character which is essential for an efficient course.

We are, Sir, yours faithfully,

ALFRED DANIELL, M.A., LL.B., D.Sc.,
DAWSON TURNER, B.A., M.D., F.R.C.P.E.,
M.R.C.P. Lond.,

Examiners in Physics for the Triple Qualification.
Edinburgh, March 31st, 1923.

THE ADMINISTRATION OF ANTI-DIPHThERITIC SERUM.

To the Editor of THE LANCET.

SIR,—May I be permitted, as one who has been for many years and still is responsible for the care of a large number of cases of diphtheria annually, to offer a few remarks on the two points connected with the treatment of that disease which have been discussed in your columns during the last fortnight? First, in respect of the intravenous injection of the antitoxic serum, of the superiority of which Dr. Poul Iversen, as you state in your annotation on p. 709, writes with such conviction. Judging by the results of experiments on animals the intravenous method should be the best. But has it been proved in practice to be so? Dr. Iversen does not help us to decide this point, for he gives no details of the therapeutic results of the cases he treated; he does not even tell us how many of his patients died; nor has he given any information as to the ages of the patients and the nature of the attacks. Apparently, however, the sole object of his paper is to show how the patients stood the injections.

Now if one thing is certain in respect of the antitoxin treatment of diphtheria it is that if patients are brought under treatment early—that is, on the first or second day—they nearly all recover and rarely suffer from complications. That result has been obtained by the method of subcutaneous injection and by the use of small and moderate doses. It would, therefore, appear to be quite unnecessary and, in view of the possibility of the occurrence of rigors and collapse such as are recorded by Dr. Iversen, even undesirable to employ the intravenous method in mild attacks. But it might be beneficial in severe cases, which are usually also late. The method was tried in a few such cases many years ago at the Eastern Hospital. I was not impressed with the results; nor was I impressed with the results of the series of 45 cases reported by Dr. J. Biernacki and Dr. J. C. Muir and the 20 reported by Dr. D. L. Cairns. There is certainly a practical objection—namely, the difficulty of getting the serum into a vein in the case of a resisting child who is suffering from a severe attack of diphtheria. In such cases the superficial veins are collapsed and empty, and it is anything but easy to get the needle into a vein and keep it there. Dr. Biernacki and Dr. Muir bore witness to the reality of this difficulty when they advocated the dissection of a vein under a general anæsthetic.

Secondly, as regards the question of dosage raised by Dr. Ker, while I am in agreement with him generally, I do not agree that the Ministry of Health are extravagant in recommending general practitioners to

administer 8000 units in cases provisionally diagnosed as diphtheria. But as my colleague Dr. Frederic Thomson, of the North-Eastern Hospital, exactly expresses my views on the subject, I need not repeat the arguments he uses in his letter to you of March 31st. Dr. Ker states that an unreasonable dread of anaphylactic shock deters many practitioners from injecting antitoxin early. That is Dr. Ker's experience in Edinburgh, but it is not mine in London. I attribute the lack of early specific treatment to two causes, the delay in waiting for the results of a culture and the failure on the part of the patient or his friends to seek medical advice at a sufficiently early moment. Dr. Ker calls attention to the remarkable fall in the case-mortality of diphtheria which followed the introduction of serum treatment and was undoubtedly effected by very moderate and even actually small doses. It may interest him and your readers to know that so far back as July, 1896, Lord (then Sir Joseph) Lister pointed out the same fact in a letter which I have in my possession, wherein he was discussing the question of the necessity of increasing the strength of the serum supplied by what was then known as the British Institute of Preventive Medicine.

I am, Sir, yours faithfully,

E. W. GOODALL.

North-Western Hospital, Hampstead, N.W.,
April 9th, 1923.

To the Editor of THE LANCET.

SIR,—In your issue of April 7th I notice a reference to an article by the late Dr. J. Biernacki and myself on this subject made in 1904. In this it is inferred that we recommended the method. I have not the paper before me, and it was written many years ago, but I have a clear recollection that we were very doubtful, after trying it in a number of cases, whether it presented any definite advantage over the usual subcutaneous method, and we practically discontinued to use it at Plaistow Hospital. I had quite forgotten that we practised giving an anæsthetic to small children for intravenous injection, and I think it must have been in a very small number of cases. I cannot help thinking at any rate that a method presents grave drawbacks if it needs a general anæsthetic in a disease like severe diphtheria, where the blood pressure and output of urine are already seriously affected and where the danger of setting up vomiting is so grave. The intravenous method would have to show very decided superiority to make habitual general anæsthesia justifiable. Yet it is precisely in small children that the gravest cases occur.

I am, Sir, yours faithfully,

J. C. MUIR.

Whipps Cross Hospital, Leytonstone, E., April 9th, 1923.

SERUM DOSAGE IN DIPHTHERIA.

To the Editor of THE LANCET.

SIR,—In reference to Dr. Claude Ker's note on this subject in your issue of March 31st, he has not taken into consideration the great differences there may be in the virulence of diphtheria in different places at different times. For the type of diphtheria present in Bristol from 1910 to 1921 doses of from 4000 to 10,000 units were in all cases sufficient to obtain arrest of the disease and disappearance of the membrane. In 1921 the type of disease suddenly altered and a type of disease arose in which the membrane still rapidly grew with the onset of great cervical oedema on giving these doses. This type was characterised by great oedema of fauces and neck and delayed formation of membrane, which frequently did not show itself until the third or fourth day, causing great difficulties in diagnosis, by which time the patient was moribund. The disease was highly infectious and many of the staff were attacked, with one death from acute toxæmia, in spite of injections totalling 30,000 units, of which 10,000 were given on the first day without influencing the disease. (These disasters are now avoided by Schick's method.) In fact, so great was

the alteration in the effect of the doses as usually administered that it was not until I had tried every kind of antitoxin on the market that I realised that the poor results of our usual doses were not due to inactive serum but to an alteration in the type of the disease. The case-mortality in this hospital has undergone three alterations since 1900: 1902-07, 6.4 per cent.; 1908-16, 4.8 per cent.; rising in 1922 to 8.2 per cent.

In this area the medical officer of health circulates all practitioners from time to time, advising the dosage which is based on the type of disease prevalent at the time. This is a far wiser plan than attempting to set standards for the whole country. The Memorandum of the Ministry of Health advocates too low dosage to arrest the type of disease still prevalent in this area, but happily now becoming less virulent. I consider that the great differences in dosage suggested by various authorities in various countries are accounted for by wide variations in virulence which may occur in this disease and has occurred during my own period of observation of the disease during the last 14 years. As regards Dr. Ker's statement that 2000 to 3000 units given in the first couple of days would produce a phenomenal fall in diphtheria mortality, our own cases here utterly disprove it for our present type of disease. Of the last 80 fatal cases in this hospital, 19 received doses of from 2000 to 10,000 units within the first 48 hours while awaiting bacteriological confirmation before admission, but these amounts were insufficient to prevent death. It is very unfortunate that an authority of Dr. Ker's eminence should be found suggesting small doses while many of us have been trying to persuade our medical brethren to give large doses. No doubt the doses suggested by him would arrest the type of disease now prevalent in Edinburgh and prevalent in Bristol from 1908 to 1921, but his doctrine would be utterly misleading if applied to the type of disease we have had here during the last two years, in which death frequently occurred within two or three days of the onset of the disease from an overwhelming toxæmia.

I am, Sir, yours faithfully.

B. A. PETERS,

Chief Medical Officer, Ham Green Hospital, Bristol.
April 6th, 1923.

BURIED RADIUM EMANATION TUBES.

To the Editor of THE LANCET.

SIR,—It is not likely that the claim of Dr. Walter Stevenson (THE LANCET, April 7th) that the use of small radium emanation tubes for medical purposes originated in Dublin will be seriously questioned. This idea has been adopted at various radium centres and the technique developed in such a way that the emanation may be concentrated in minute glass capillaries measuring no more than about 3 mm. long and 0.5 mm. diameter. Dr. Failla, of the Memorial Hospital in New York, has devised a piece of apparatus for this purpose which is little short of a triumph of experimental skill. By the use of emanation in this way, the risk of loss of radium is probably minimised, although accidents have happened in the past to glass vessels containing radium in solution. A further apparent advantage is that tubes of any desired strength or dimensions may be filled to meet clinical requirements. This is not possible if the available supply of radium is sealed into a number of platinum tubes arbitrarily graded in strength.

A few disadvantages of the method may be mentioned. The cost of the apparatus, its upkeep, and the personnel for its efficient working is considerable; the emanation tubes slowly decline in strength, and this makes the calculation of the dose a little tiresome. Dr. Regaud has thought it more useful to measure the quantity which he calls "l'émanation détruite" instead of the average strength of the emanation, though the latter appears more directly useful.

I think that these obvious pros and cons are readily granted by those who have practical experience in the subject. There are, however, some debatable points which it might be useful to mention briefly.

(a) *The Uniform Irradiation of a Tumour by the Surgical Introduction of Radio-active Tubes.*—I presuppose that it is desired to give each part the same dose, presumably the lethal dose. The question is, What are the best sources to use for this purpose? We must avoid point sources and sources giving easily absorbed radiation; here are two objections to the emanation capillaries. If platinum tubes of thickness 0.5 mm. are used, the bulk of the radiation is of a very penetrating character, and some approach to uniformity of irradiation is got by using a number of them suitably placed; purely geometrical requirements must, however, give way to what is possible surgically. The lack of uniformity of irradiation can be compensated to some extent by the external application of gamma rays, but it appears hardly possible to avoid the overdosing of the tissues in those zones which are in immediate contact with the tubes.

(b) *The Avoidance of Tissue Reactions of an Undesirable Nature.*—Dominici held that it was a good thing to avoid the actual destruction of the tissues irradiated, and he aimed at producing a reaction in the normal tissues of the host which would bring about the desired results; he was a strong advocate of gamma radiation. Lately Dr. Laborde has maintained that the rather violent changes induced in the tissues by the beta rays from the emanation capillaries is an argument against their use.

(c) *The Advantages of Using Sources of Constant Intensity.*—Advances in radium therapy depend not only upon a recognition of the forms of disease for which it is a suitable agent, but upon the quantitative way in which it is applied; the quantitative technique is perhaps just as difficult as that involved in the deep X ray therapy of the present day, and it might serve a useful purpose in radium therapy if there were some agreement among those interested in the surgical use of radium to use tubes graded in size and content, according to a definite scale. The quantities at different centres in ordinary use range roughly from 1 to 100 mg. of radium bromide, and if arbitrary quantities, say, 1, 10, 25, 50, and 100 mgm. were decided upon and placed in tubes appropriate in size to these contents, comparisons between the results of treatment at different centres would become simplified to some extent.

In the radium clinical investigation which is at present being conducted at different centres in Great Britain and Ireland under the ægis of the Medical Research Council the attempt has been made to do this.

I am, Sir, yours faithfully,

SIDNEY RUSS.

The Middlesex Hospital, London, April 9th, 1923.

ALCOHOL AND INSANITY.

To the Editor of THE LANCET.

SIR,—Dr. Sullivan refuses to differentiate between a concrete instance and an abstract principle. It is not of the smallest importance from the present point of view whether or not mental stress is a cause of insanity. Dr. Sullivan will not, I suppose, deny that there is *some* cause of insanity. Let us call it "x" and I will grant him that mental stress has no causal connexion with insanity. Then "x" stands for any and every cause of insanity except alcoholism, and the point at issue remains unchanged. In order to prove that alcoholism is not a cause of insanity, it is necessary to show (in addition to the facts originally adduced in your leading article) that "x" has not increased in proportion to the diminution in alcoholism. This neither Dr. Sullivan nor your leading article has made any attempt to do.

I am, Sir, yours faithfully,

Wimpole-street, W., April 9th.

STANLEY WYARD.

INSANITY AND THE CRIMINAL LAW.

To the Editor of THE LANCET.

SIR,—In your admirable leading article on Insanity and the Criminal Law in THE LANCET of April 7th, you state that "a committee of the Medico-Psychological Association, which considered this question exhaustively in 1896, failed to find, within the period covered by its inquiry, any instance of miscarriage of justice." As I opened the discussion on this subject in 1894 at the annual meeting of the British Medical Association at Bristol, at which for the first time in the annals of the B.M.A. barristers and lawyers were invited to attend and join in the debate, and as the said committee was appointed on a resolution proposed by myself and seconded by the late Dr. Charles Mercier, may I be allowed to interpose?

The report you mention was strongly opposed by a minority, and the result of this opposition was, that a resolution was carried by a large majority—that the report be laid on the table. So that this report was never accepted by the Medico-Psychological Association. My one great objection to the M'Naughton ruling—apart from its unscientific determination—is that the evidence which experts are *allowed by some judges* to give in the criminal court is not sufficient to enable the jury to bring in a verdict of "Guilty, but insane." Yet in many cases a written opinion by the same or some other expert, who is not cross-examined after an examination of the condemned prisoner, is sufficient to save him or her from the scaffold. Justice which is now done the prisoner in the condemned cell was withheld from him in the criminal court. This is, to my mind, palpably wrong and should in some way be righted.

The question of diminished responsibility is a very important one and this question would be easy of solution if we had—like other countries—degrees of the crime of murder.

I am, Sir, yours faithfully,

April 6th, 1923.

LIONEL A. WEATHERLY, M.D.

SYPHILIS OF THE MEDIASTINUM.

To the Editor of THE LANCET.

SIR,—Whilst duly appreciating Dr. F. G. Chandler's friendly criticism of my case, I feel bound to confess that some of the points he has raised as being typical of mediastinal sarcoma are not in keeping with the teaching of medical writers. More especially do I refer to the statement that in mediastinal sarcoma there is "no displacement of viscera." Practically all the authorities to whom I have gone for reference state that displacement is an early symptom and may assume very large proportions. With regard to the title of my paper, I should have used the terms "A Case of Aneurysm of the Aortic Arch in a Girl," had I not been impressed by the unlikelihood of such a condition in a young female. As it was, X ray examination almost suggested the presence of an aneurysmal dilatation. I also regret that a post-mortem examination could not be obtained.

I am, Sir, yours faithfully,

Doncaster, March 26th, 1923.

HAROLD F. RENTON.

THE DISPENSING OF PRESCRIPTIONS.

To the Editor of THE LANCET.

SIR,—I have been interested in the subject of accuracy in dispensing referred to in letters recently appearing in THE LANCET and wish to add my testimony in support of the opinions expressed by the writers as to the necessity of this matter receiving more general attention under the Food and Drugs Acts. One of your correspondents rightly says "how many mistakes may be made through faulty drugs?" and pleads for a set of regulations similar to those which control the dairy. I think the powers we

already possess are quite sufficient if they are properly used. An Islington paper, the *Daily Gazette*, of March 24th, records a successful prosecution for the sale of a certain compound drug which was not composed of the ingredients in accordance with the demands of the purchaser, inasmuch as the said compound contained potassium bromide to the extent of 20.3 per cent. in excess of the amount prescribed, and spir. ammon. aromat. to the extent of 28.6 per cent. in excess of the amount prescribed.

When in the Isle of Wight in the year 1913, a sample prescription was made up by six panel chemists, the sample being taken with a view to ascertaining how they would be made up, particularly as regards quantities of materials composing the mixture. The prescription was a very simple one, containing nothing but potassium iodide, glycerine, and water. The iodide cost then about 13s. 6d. a pound, and the glycerine about 1s. 3d. a pound. The results of the analyses showed that the drugs were genuine, but that the quantities supplied varied very considerably.

Sample.	Short in pot. iod. (per cent.).	Short in glycerine (per cent.).
(a) was	3.75	10.96
(b) was	9.25	6.03
(c) was	16.5	27.3
(d) was	11.75	12.92
(e) was	6.0	2.7
(f) was	3.5 per cent. in excess of pot. iod. and 29.5 per cent. in excess in glycerine.	

Such results show the need of making frequent investigation into the accuracy of the dispensing of drugs by chemists.

I am, Sir, yours faithfully,

J. P. WALKER,

April 5th, 1923.

County Medical Officer, Isle of Ely.

L'AFFAIRE SPAHLINGER.

To the Editor of THE LANCET.

SIR,—Having read in your columns the opinions of several of my colleagues concerning Mr. Henry Spahlinger's antituberculous vaccines and sera, I beg to inform you that I have applied this method since 1915 to more than 250 patients. My reasons for not having published sooner the remarkable results obtained are as follows.

These specific remedies are extremely delicate and difficult to produce. They necessitate the simultaneous manufacture of a series of partial products of which the combination produces the necessary polyvalence in order to obtain a cure for tuberculosis. The supply of these sera and vaccines has often, partially or totally, failed by reasons of the war and financial difficulties. Had the public been aware of the favourable results obtained by the treatment, the visits and demand for the remedy would have rendered Mr. Spahlinger's work more difficult and delayed the manufacture. The antitoxic action of the sera and their polyvalence not only arrest tuberculosis in its acute forms, but also render possible the application of this treatment with success in the most advanced phases of the disease, and in cases in which any therapeutic intervention by methods previously known would have appeared hopeless. The curative effect of the vaccines, even of partial vaccines, in chronic forms of tuberculosis has shown itself extremely reliable.

Since, for want of funds, the sera and vaccines can no longer be prepared, and, owing to general indifference, there is a prospect of closing the laboratory (the continued activity of which involves the recovery and lives of a multitude of sufferers) I consider it now to be my duty to make known the results obtained by this method.

I am, Sir, yours faithfully,

DR. TH. STEPHANI.

Montana, Switzerland, April 6th, 1923.

THE OPERATIVE TREATMENT OF SEPTIC MENINGITIS.

To the Editor of THE LANCET.

SIR,—The correspondence which has taken place upon the above subject, although it may not have cleared up the more or less academic point at issue, has at all events focused attention upon the all-important necessity of early diagnosis and early surgical interference.

How far one clinician will rely upon early biochemical evidences of disease and how long another will await the advent of definite objective indications will, no doubt, depend largely upon what his previous teaching has been. Nothing which has been written in this correspondence has altered my opinion that there is in meningitis a stage when the exudate is "serous" and another when it is "purulent"; that the one is the forerunner of the other, the former condition being amenable to early operative treatment, the latter, except on rare occasions, being followed by a fatal result.

I have had occasion to criticise Prof. Holgar Mygind's statistics on a previous occasion and do not propose to discuss them again. I would suggest, however, that those in charge of aural clinics—for I am referring to otitic meningitis—tabulate all the cases passing through their hands during a period of 12 months, and then publish the chemical changes found in the cerebro-spinal fluid, the cellular content, the bacteriological findings, and the final results. If they adduce evidence contrary to my experience I shall ask them to allow me to sit at their feet and learn.

I am, Sir, yours faithfully,

Manchester, April 9th, 1923.

WILLIAM MILLIGAN.

ALLOCATION OF PANEL PATIENTS.

To the Editor of THE LANCET.

SIR,—The injustice of not allocating insured patients, who will not take the trouble to choose a doctor, is shown by the following. In the town where I practise there are 22,641 patients on the panel, 2888 of these have chosen no doctor, and the grant for them (some £1400 per annum) is divided among the insurance practitioners according to the numerical strength of their panels. In the town is a "Dr. A," with a panel of over 4000; he is allowed to have an arrangement with "Dr. B" (although not his assistant or even his partner) to cover this excess, and the two are allowed to have a total list of 4500; they actually have 4700 odd as a total. These two practitioners will get, roughly, one-fifth of the £1400 per annum (£280) above-mentioned as their share, in addition to the grant for their actual lists. If these 2888 patients were allocated "Drs. A and B" could not possibly receive any of them, as their lists are already in excess.

I am, Sir, yours faithfully,

April 9th, 1923.

PANEL PRACTITIONER.

ROYAL WEST SUSSEX HOSPITAL, CHICHESTER.—The excess of expenditure over income in 1922 was £564, compared with the deficit of £196 11s. 7d. during 1921. In their annual report the governors appeal to all newcomers in the district to support the hospital, and to all employed persons to join the employee's scheme and to give a weekly contribution of 1d. or 2d. The scheme introduced last year for private paying patients is said to be working satisfactorily. The hospital has been adopted by the General Nursing Council of England and Wales as an approved training school for nurses, and an extensive new curriculum for student nurses has been instituted. The private nursing branch has been discontinued owing to the small number of applications received, private nurses in the district being well supplied from other sources. Sanction was given to liquidate the deficit from the Trustees' Fund which, it was stated, now stands at £16,759. A committee has been appointed to consider means of increasing the income. In-patients during the year numbered 954, against 928 during 1921; out-patients 1020, against 1088; X ray patients 815, against 497. The work of the X ray department had so increased that an X ray sister has been appointed.

Medical News.

LONDON SCHOOL OF TROPICAL MEDICINE.—The following candidates successfully passed the examination held at the termination of the seventy-first session (January to March, 1923):—

*A. G. Harsant (Duncan medal). *R. Briercliffe, *C. E. Cook, *H. de Boer, *E. W. Adcock, C. H. Han, A. C. Rebello, R. H. Simpson, H. C. Godding, C. de C. Martin, M. L. Dhawan, J. Wijeyeratne, F. S. T. Thomas, J. M. Ghosh, R. W. C. Kelly, W. J. Jameson, P. Walsh, S. A. Wilkinson, H. G. Stockley, A. H. Manfield, Miss N. R. Mucadam, E. V. Lupprian, K. S. Krikorian, R. Cross, A. C. Garewah, H. P. Hodge, E. D. Lindow, and V. Mathew Matthews.

* With distinction.

UNIVERSITY OF DURHAM.—A new degree of Doctor of Surgery (D.Ch.) has been instituted at this University. The degree will be granted to those who can offer evidence that after graduation they have complied with the following regulations:—

The candidate must be a registered medical practitioner, not less than 24 years of age.

He must devote three years, not necessarily consecutive, subsequently to obtaining a registrable qualification, to the study of surgery and ancillary subjects. One at least of the three years must be spent in the University.

The candidate must submit to the professor of surgery the course of study he proposes to follow, and this course must be approved by the Board of the Faculty of Medicine.

One year shall be devoted mainly to work in the departments of anatomy, physiology, pathology, and bacteriology.

Six months must be spent as resident surgeon in a recognised teaching hospital and six months in the study of surgery in a recognised medical centre.

Six months must be spent in surgical study abroad.

The examination shall consist of an essay on some surgical subject chosen by the candidate and approved by the professor of surgery, and a clinical, practical, and oral examination in the field of general surgery, including anatomy, physiology, pathology and bacteriology, operative surgery, bandaging, instruments, &c. Further particulars may be obtained from the Registrar at the University.

At the Convocation held on March 29th the following degrees were conferred:—

M.D. for Practitioners of 15 Years' Standing.—William H. I. Bathurst, Walter G. Edwards, and William O'Sullivan.

M.B., B.S.—Frederick J. Armstrong, Sydney Basham, Thomas H. Blench, John C. Boyde, Edward C. Brewis, Cecil J. Cellan-Jones, William N. Douglas, Mary Douglass, Claude Fenwick, Clennell C. Fenwick, William Graham, Alec Hanson, Norman Harkness, Edward S. Kirkhouse, Ralph R. Scott, Ralph F. Tredre, Henry F. Wattsford, and Edward A. Welsh.

L.D.S.—Thomas W. Hogg, Julius H. Joseph, Alfred E. Pattie, Eric B. Phillips, John L. Reid, and Allen McLean Wilson.

UNIVERSITY OF DUBLIN, SCHOOL OF PHYSIC, TRINITY COLLEGE.—At examinations recently held the following candidates were successful:—

FINAL MEDICAL EXAMINATION.

Part I., *Materia Medica and Therapeutics; Medical Jurisprudence and Hygiene; Pathology and Bacteriology.*—

*Gordon Purdy, *Wilfred H. Anderson, *James W. Wallace, *George A. Cowan, Patrick K. Dixon, Douglas L. Hemmingway, Rudolf Schaffer, Cornelius J. N. Loubser, John A. MacDonnell, John Crawford, Agnes L. Kelly, Joseph Morris, Godfrey W. Garde, Anthony B. Monks, Ralph A. Webner, George R. L. Jordan, Howard St. George McKenny, Jerreth Horwich, George G. McFarland, Morris Sless, William D. Speedy, Robert G. F. Thompson, John G. Maguire, Pieter Coetzee du Plessis, John E. Beatty, James Craig, John L. Livingston, Herbert Birney, James L. Marshall, Alexander Hawthorne, Paul Douglas Piel, and Isobel G. Smith.

Part II., *Medicine.*—William S. Dixon, Reginald R. J. Brandt, Joseph A. Gaynor, Agnes McLaughlin, Samuel M. Geffen, Robert T. Jackson, Alice M. A. Downing, Wilfrid E. C. Wynne, Henry O'Donnell Burke-Gaffney, George F. T. Saunders, James A. MacDonald, Henry J. L. Murphy, Jack M. Gordon, Ely G. Copeland, Dorothy C. H. Dornan, Herbert Kohlberg, Robert S. McElroy, Bernard Morris, William E. Callanan, Margaret L. Cowan, Norah M. Gilchrist, Maria E. Wagener, Max Wulfschön, Eileen A. Boyd, Samuel W. Jamison, Hyman S. Roseman, Johannes H. Stals, and Joseph C. Byrne.

Surgery.—*Jan Hendrik Rauch, *Agnes McLaughlin, Richard R. D. Crawford, Robert H. Micks, Victor O. McCormick, Harold Renton, Cecil A. V. Ovendale, David S. Spence, Reuben Lipschitz, William T. Hogan, Henry M. Martin, John C. St. George Earl, Joseph E. Deane, Jan Hendrik Hodgman, Nicolaas Jan Valkenburg van Druten, Alexander Bernstein, Mossy Jaffe, William L. Duncan, Thomas G. Wilson, Ely G. Copeland, John S. Glasgow, Ernest M. Landau, James V. Williams, Albert V. Wood, Margaret L. Cowan, John H. J. Stuart, Etienne R. Hafner, Frederick W. G. Smith, Hugh R. Brady, Harold Lewin, Jacobus F. van Staden, and John D. Watson.

Midwifery.—John S. Glasgow, Joseph E. Eliason, Lazarus Heyman, William L. Duncan, John Kalmanson, Eric C.

Downer, Samuel M. Geffen, Kathleen E. Hill, Max Wulfsohn, John McClelland, Richard C. L. Griffiths, Herbert Kohlberg, Israel Marin, Albert E. O'Donnell, Frederick W. G. Smith, Norman E. H. P. Williams, Louis MacSherry Bell, Frederick T. Easby, Henry O'Donnell, Burke-Gaffney, James A. MacDonald, Alexander Hawthorne, Nicolaas Jan Valkenburg van Druten, Tobias Freedman, Robert A. O'Meara, Johannes H. Stals, Pieter Coetzee du Plessis, Charles W. J. Ingham, Solomon Narunsky, Harry Ruben, Joseph C. Byrne, Morris Cohen, Louis Harris, William T. Hogan, Gladys Weatherill, Martha Reid, Frederick G. Brown, Sylvia B. Wigoder, Charles R. Hillis, Albert V. Wood, Robert S. McElroy, Julius Kruger, and Cecil J. McQuillan.

* Passed on high marks.

DIPLOMA IN PUBLIC HEALTH.

Part I.—Leon O. Vercueil, Ruth F. Flavelle, Mary M. O'Leary, Samuel G. Weldon, and Patrick M. J. Bobbett.

Part II.—Leon O. Vercueil, Ruth F. Flavelle, Samuel G. Weldon, and Mary M. O'Leary.

NAVAL MEDICAL COMPASSIONATE FUND.—The annual meeting of the subscribers to this Fund will be held at the Medical Department of the Navy, 68, Victoria-street, London, S.W., on Tuesday, April 17th, at 11.30 A.M., for the purpose of electing six directors.

CONGRESS OF OBSTETRICS AND GYNÆCOLOGY.—An alteration is announced in the programme of this congress which will be held in Edinburgh on April 19th and 20th. It has been found impossible to issue any formal report as a basis for the main discussion on intrinsic dysmenorrhœa and its treatment. The subject will therefore be introduced by Prof. Blair Bell, Liverpool, while Dr. T. Watts Eden, Prof. Ewen Maclean, and Dr. R. W. Johnstone will follow with brief papers on special aspects of the question.

SOCIETY OF MEDICAL OFFICERS OF HEALTH: FEVER HOSPITAL MEDICAL SERVICE GROUP.—A meeting of this group will be held at 1, Upper Montague-street, Russell-square, London, W.C., on Friday, April 27th, at 3.45 P.M. A paper will be read by Dr. W. J. J. Stewart on the Failure of the Isolation Hospital to Reduce the Incidence of Scarlet Fever; a Possible Explanation and Remedy, with a note on Diagnosis. Dr. M. O. Howell will communicate a report on a case.

ROYAL INSTITUTE OF PUBLIC HEALTH.—The next Congress of the Institute will be held at Scarborough from Wednesday, May 16th, to Monday, May 21st inclusive, under the presidency of Lord Riddell. The President will be supported by an imposing list of vice-presidents, including the Presidents of the English Royal Colleges, the director of the Royal Naval Medical Department, the chairman of the Metropolitan Asylums Board, and the mayors of a large number of metropolitan boroughs and provincial cities. The Mayor of Scarborough will preside over a general committee, composed of representative citizens of the locality. The proceedings will be divided into five sections—namely: (1) State Medicine and Municipal Hygiene; (2) Naval, Military, Air, and Tropical Diseases; (3) Bacteriology and Biochemistry; (4) Women and Public Health; and (5) Industrial Hygiene, and to the proceedings of these sections important communications have already been promised. All information with regard to hotel and travelling arrangements and railway tickets should be made to Dr. T. N. Kelynaek at the office of the Institute, 37, Russell-square, London, W.C.

ROYAL SANITARY INSTITUTE.—A sessional meeting will be held jointly with the Home Counties Branch of the Society of Medical Officers of Health, on April 27th, in the Guildhall, Guildford, when a discussion on Things That Matter in Public Health will be opened by Sir Arthur Newsholme, followed by Sir Arthur Spurgeon, Dr. Andrew Balfour, Alderman Shawcross, Dr. G. F. Buchan, Dr. R. J. Ewart, Dr. A. Greenwood, Dr. W. W. Jameson, Dr. D. C. Kirkhope, Dr. A. Lyndon, Dr. A. B. McMaster, Dr. T. S. McIntosh, Dr. W. A. Muir, Dr. R. D. Smedley, and Dr. J. Watt. The chair will be taken at 6 P.M. by Dr. Louis C. Parkes. Those proposing to attend should notify the hon. local secretary, Dr. J. Cates, 5, Grove-crescent, Kingston-on-Thames, not later than April 20th.

The annual congress will be held at Hull from July 30th to August 4th. The inaugural address will be read by the President of the congress, Mr. F. R. Ferens, high steward of Hull, on July 30th. A lecture on a Pure Water-supply will be delivered by Sir Alexander Houston on July 31st. A Health Exhibition, illustrating municipal sanitation and domestic health and comfort, will be arranged, and visits to places of sanitary interest. The Council invite papers on health and sanitary science. Authors should forward the manuscript, which should not exceed 2000 words, as early as possible, in any case not later than June 25th, to the Secretary, the Royal Sanitary Institute, 90, Buckingham Palace-road, London, S.W. 1, from whom further particulars may be obtained. The hon. local secretaries are Mr. H. A. Learoyd and Dr. J. Wright Mason.

SOCIETY FOR CONSTRUCTIVE BIRTH CONTROL AND RACIAL PROGRESS.—A meeting will be held on April 19th, at 8 P.M., at Essex Hall, Strand, London, W.C., when Mr. Charles E. Pell will give a lecture entitled "Is the Fall in the Birth-rate a Natural Law?" to be followed by a discussion. Those interested are asked to apply to the hon. sec. of the society, 7, John-street, Adelphi, London, W.C. 2.

No. 55 GENERAL HOSPITAL.—The annual reunion dinner will be held at the Trocadero Restaurant on Saturday, May 12th, at 7 for 7.30 P.M. The matron and nurses are holding a reunion tea at the United Services Club, 34, Cavendish-square, at 4-6 P.M. on the same day, to which all officers are invited. Those intending to be present are asked to notify Dr. H. B. Roderick, 17, Trumpington-street, Cambridge, as soon as possible.

LADIES' MEDICAL GOLFING SOCIETY.—The spring meeting was held at West Hill golf course on April 6th. The Canny Ryall Challenge Cup was won by Mrs. Max Page with a score of 92-10=82. Miss M. Gourlay won the scratch prize with a score of 88. Miss E. Leitch won the senior handicap with a score of 89-6=83, and with Mrs. Lamplough the foursomes against bogey (2 down). Miss McElroy (18) won the junior handicap after a tie with Mrs. Sherwill Dawe (20), with a score of 88.

ST. BARTHOLOMEW'S HOSPITAL WAR MEMORIAL FUND.—At a recent meeting of the Council of the Medical College it was decided to open a subscription list towards the memorial for St. Bartholomew's men who lost their lives during the European War. The exact form which the memorial should take has not yet been decided upon, but it would in any case include a tablet on which the names would be recorded. A provisional list has been drawn up and circulated in order that any mistakes or omissions may be rectified. The preliminary list of subscriptions includes a sum of £1000 from the medical staff of the hospital. Any who wish to subscribe are asked to send their contribution to Mr. W. Girling Ball, hon. secretary, 77, Wimpole-street, London, W. 1.

LANDOUZY MEMORIAL MUSEUM.—On March 22nd the Landouzy Memorial Museum was officially opened, the ceremony taking place in the council room of the Faculté de Médecine. Most of the professors of the faculty were present, and many offered grateful tribute to the late doyen of the French medical profession. His successor, Prof. G. H. Roger, referred to the time, now happily remote, when Landouzy's views on the prevalence of tuberculosis were the subject of incredulous scoffing. His opinion that almost every obscure case of pleurisy was due to tuberculosis gave him the reputation for seeing tuberculosis everywhere. To which accusation he would retort: "But it is everywhere." Other speakers dealt with other aspects of Landouzy's career—his gift for organisation, his clinical acumen, his patient kindness. But always, or nearly always, they came back to his work on tuberculosis, and his labours on behalf of the "tuberculosis casualties" of the war were referred to more than once. The medal struck in commemoration of Landouzy bears the words: Quid medicus possit vita verboque docebat.

THE DISPENSING OF PRESCRIPTIONS IN SALFORD.—A report issued by Mr. G. D. Elsdon, borough analyst of Salford, records the success achieved in Salford by the superintendence of dispensing under the Insurance Act. For many years past mixtures based upon prescriptions written on the private notepaper of medical practitioners have been analysed in Salford. In 1916 a clause was inserted in the terms of service under the Insurance Act for persons supplying drugs and appliances, which stated that:

"All drugs and appliances shall be supplied to the person presenting such order as aforesaid free of charge to that person. Provided; nevertheless, that the pharmacist shall sell to any one of the persons mentioned in Section 13 of the Sale of Food and Drugs Act, 1875, or to any person authorised by such person at the price usually charged to private customers any drug or medicine prescribed or specified on the appropriate prescription form provided by the Committee for the use of insured persons and signed by an insurance practitioner."

In 1918 arrangements between the Salford Insurance Committee, the Salford Health Committee, and the Pharmaceutical Association were made for the taking of samples on Insurance Act prescription forms. It is important to decide what degree of accuracy it is reasonable to expect, and in Salford it has been mutually agreed that the strength of prescriptions should not differ by more than 10 per cent. from the truth, except in such cases as sodium bicarbonate, when 15 per cent., or thereabouts, was accepted. In the case of potent drugs, however, it was insisted that a 10 per cent. error was too great. The public analyst reports to the Insurance Committee as well as to the Health Committee, so that either or both may institute legal proceedings should it deem fit.

THE address of the Medical Defence Union has been changed to 49, Bedford-square, London, W.C. 1.

Sir David Wallace, K.B.E., C.M.G., F.R.C.S., has been appointed a deputy lieutenant for the county of the city of Edinburgh.

PRECAUTIONS AGAINST SMALL-POX AT NELSON.—In consequence of the outbreak of small-pox at Nelson—up to the end of last week 49 cases have been reported—the managers of public entertainments and the local cinema houses have agreed to close their establishments. The Sunday schools also will be closed.

MANCHESTER HOSPITALS.—The Manchester and Salford Hospital Saturday and Convalescent Homes Fund and district joint committees last year collected £15,882, an increase of £1000 on the previous year. The increase was due to the penny-a-week scheme, which the chairman described as the solid rock foundation of the Hospital Saturday Fund. Since its institution in 1907 the Fund has provided £83,600 for the hospitals.

DONATIONS AND BEQUESTS.—The late Mrs. Frances Brown, of Clapton-square, Clapton, N.E., has left by will, among other bequests, £5000 to King Edward's Hospital Fund for London, for the use of such London hospitals as may be most in need of it; £5000 to the London Hospital; £5000 to St. Bartholomew's Hospital; £2000 to Addenbrooke's Hospital, Cambridge; £1000 to Dr. Barnardo's Homes; £1000 to St. Dunstan's Hostel for Blinded Soldiers.

THE LATE DR. DANIEL BALDING.—Daniel Barley Balding, who died on April 8th at Royston, Herts, at the age of 92 years, studied medicine at the Middlesex Hospital, qualifying L.S.A. in 1852 and F.R.C.S. Eng., 1858. He became resident medical officer at his hospital and maintained throughout life a keen interest in its doings, contributing notes on the Hospital Reports to our columns. He was on the Commission of Peace for the counties of Cambs and Herts, and had acted as coroner for Hertfordshire for 40 years.

CITY OF LONDON MENTAL HOSPITAL.—In the annual report for 1922 of this hospital, which is situated at Stone, near Dartford, it is recommended that two clauses relating to the hospital should be inserted in the next General Powers Bill of the Corporation of London. The first of these is to authorise the use of the term "mental hospital" in describing the institution for legal and official purposes; the visiting committee "believe that they are only voicing a general feeling throughout the country that the description 'asylum' should be dropped in connexion with institutions for the mentally afflicted." The second is to empower the institution to receive voluntary boarders; many applications for the admission of voluntary boarders are received, and have at present to be refused. A noteworthy feature of the report concerns the practice of allowing unusually large numbers of patients out on trial and on parole. A considerable amount of anxiety and trouble is thus involved, but the pleasure and gain to the patients are such that 86 have been allowed out on parole this year, and a number of others have been given leave of absence, not only to test fitness for discharge, but in some cases to give them the benefit of a change during remissions in their illness.

A TOUR OF THE ITALIAN SPAS.—An opportunity will be afforded at the end of next month for a group of English medical men to visit a selection of the Italian spas. The departure from London will take place on May 29th, and the arrangements on the British side are in the hands of Major W. Stormont, Italian State Railways and State Tourist Department, 12, Waterloo-place, London, S.W., from whom all details can be obtained. The tour, which will last a fortnight, is being organised in connexion with the Italian medical authorities; it will start at Acqui, just north of Genoa, and will include San Pellegrino, Sirmione, Levico, Roncegno, Salsomaggiore, Montecatini, Fiuggi, and Agnano, next to Naples. Incidentally the tour will take the travellers through Milan, Florence, and Rome on their way south. Owing to the generosity of those concerned the train and hotel accommodation from beginning to end will cost only about 12 guineas, to which sum will have to be added another 12 guineas, or so, for the journey between London and the starting-point. The Italian spas are not at all well known to English medical men, and the opportunity is one therefore that should be taken by those particularly interested in balneological treatment. The most lovely season of the year has been selected for the tour, and arrangements have been made for Italian medical men with a knowledge of English to accompany the travellers.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

Defeat of the Government.

THE Government suffered defeat in the House of Commons on Tuesday evening, April 10th, after a discussion on the motion that "the Speaker do now leave the Chair" on the House going into Committee of Supply on the Civil Service Estimates.

HOUSE OF COMMONS.

MONDAY, APRIL 9TH.

Dangerous Drugs and Poisons Bill.

On the motion for the third reading of the Dangerous Drugs and Poisons (Amendment) Bill,

Mr. SIDNEY WEBB said he had been asked by a number of medical practitioners to bring several points to the notice of the Home Secretary in connexion with the measure. There had been considerable advances made in the knowledge concerning drugs and poisons since the Poisons and Pharmacy Act, 1868, was passed. He suggested that it might be possible to draw up a revised schedule of these substances with the advice of the Royal Colleges of Physicians and Surgeons in the light of the latest chemical knowledge available. He also called attention to the powers taken under the Bill to deal with acts which might not be crimes under British law, but might be made punishable under the law of other countries. He thought that this was stretching our system of jurisprudence rather far. While he did not suggest that anything dreadful was going to happen under this provision it seemed to him to be opening the door rather wide.

Sir SYDNEY RUSSELL-WELLS said that he was convinced that the provision with regard to offences under the law of foreign countries was absolutely necessary if conventions were to be entered into with other nations for the suppression of what was undoubtedly a pernicious practice. He thanked the Home Secretary on behalf of the medical members of the House for the way in which he had treated the representations they had made to him on this measure. He thought that Mr. Bridgeman had realised they were anxious to help in carrying out the objects of the Bill. He thanked the right hon. gentleman for removing the provision which prevented medical men from prescribing these drugs for themselves. They had been able to convince the Home Secretary that the provision would occasion inconvenience and hardship and all sorts of anomalies, and would not be likely to effect the object in view.

Mr. BRIDGEMAN (Home Secretary) said that he was taking steps to withdraw the regulations referred to by the hon. Member. As to the question of a revised schedule raised by Mr. Sidney Webb, the schedule made up under Section 2 of the original Act was brought down to 1908. On the advice of the Pharmaceutical Society it would be possible to add other drugs to the schedule if it was found necessary. In reply to Mr. Webb's point about laws passed in other countries, Mr. Bridgeman said that the agreement signed at The Hague on Jan. 23rd, 1912, should do away with any apprehension that foreign countries might pass some law which we should be obliged to observe.

Mr. G. C. CLAYTON asked the Home Secretary to make the same concessions to licensed wholesale druggists as he had made to the medical profession and the Pharmaceutical Society. At present they were liable to the same penalty as illicit drug dealers.

Mr. BRIDGEMAN said that that point was raised in Committee, and on that occasion he gave reasons why he could not agree to reduce the penalty for a breach of the licence far below what he thought was necessary.

Lieut.-Colonel FREMANTLE said that this was not "stunt" legislation; he only wished it were. But they were faced with a very serious danger. The drug traffic was a subtle, insidious influence which was sapping the vitality of individuals met with in ordinary life. The long-standing trouble between the medical profession and the makers of patent medicines was removed by the provisions of this Bill. The claim of the profession that the ingredients of patent medicines should always be given was opposed by the makers on the ground that it would not be in the interests of British trade to reveal trade secrets. Both claims were satisfied, and the public interest met by the provision that in patent medicines containing a dangerous drug the proportion of that drug must be stated on the bottle.

Dr. CHAPPLE said that the Bill dealt with only one-tenth of the evils of the drug traffic. He urged the Government to complete their work by bringing in legislation on the basis of the report of the Committee on Patent Medicines, which was presented in 1914.

The Bill was read a third time.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Tuesday, April 17th.

GENERAL MEETING OF FELLOWS: at 5 P.M.

Ballot for election to the Fellowship.

ORTHOPÆDICS: at 5.30 P.M. (Cases at 5 P.M.)

Cases:

The following will be shown by:—

Mr. C. Max Page: Cases of Muscle Sliding Operation on Forearm.

Mr. P. Bernard Roth: (1) Case of Renal Dwarfism after Operation for Genu Valgum. (2) Case of Ocular Torticollis.

Other cases will be shown.

Wednesday, April 18th.

HISTORY OF MEDICINE: at 5 P.M.

Papers:

Dr. A. T. Davies: Thomas Davies, M.D., and His Work.

Mr. R. Campbell Thompson: Assyrian Medical Texts in the British Museum.

Thursday, April 19th.

DERMATOLOGY: at 5 P.M. (Cases at 4.30 P.M.)

Cases will be shown.

Friday, April 20th.

OTOLOGY: at 5 P.M. (Cases at 4.45 P.M.)

Communication:

Mr. E. D. Davis: The Morbid Anatomy and Drainage of Otitic Meningitis (with specimens).

Cases:

Sir James Dundas-Grant will show cases of Deafness with History of Injury.

Cases will be shown by Dr. Dan McKenzie and others.

ELECTRO-THERAPEUTICS: at 8.30 P.M.

Short Papers:

Dr. Salmond: A Case Illustrating the Use of Pneumopericardium.

Mr. Hart and Mr. W. Whately Smith: A New Apparatus for Measuring Sensori-motor Reaction Times.

Other papers will be read.

ANÆSTHETICS: at 8.30 P.M.

Annual General Meeting:

Election of Officers and Council for 1923-24.

To be immediately followed by an ordinary meeting at which Dr. J. H. Chaldecott will open a discussion on Coroners' Inquests: The Classification of Anæsthetic Deaths as Violent or Unnatural. Members of the Coroners' Society and the Medico-Legal Society have been invited to attend and take part in the discussion.

LONDON DERMATOLOGICAL SOCIETY, 49, Leicester-square, W.C.

TUESDAY, April 17th.—4.30 P.M., Specimens and Cases. 5 P.M., Dr. R. Prosser White: Fur Dermatitis.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, London, W.C.

MONDAY, April 16th.—5 P.M., Prof. Shattock: Specimens Illustrating Repairs of Fractures.

FRIDAY, 5 P.M., Sir Arthur Keith: The Shape and Relationships of the Stomach.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith-road, W.

MONDAY, April 16th.—10 A.M., Mr. MacDonald: Genito-Urinary Dept. 3 P.M., Mr. Simmonds: Surgical Out-patients. 3 P.M., Mr. Simson: Diseases of Women.

TUESDAY.—10 A.M., Mr. Steadman: Dental Dept. 12 noon, Dr. Burrell: Chest Cases. 2 P.M., Mr. Banks Davis: Nose, Throat and Ear.

WEDNESDAY.—10 A.M., Dr. Saunders: Medical Diseases of Children. 2.30 P.M., Mr. Donald Armour: Visit to Surgical Wards. 3 P.M., Dr. Pernet: Skin Dept.

THURSDAY.—2 P.M., Mr. Bishop Harman: Eye Dept. 2 P.M., Mr. MacDonald: Genito-Urinary Dept. 3 P.M., Dr. Scott Pinchin: Medical Out-patients.

FRIDAY.—10 A.M., Dr. Drummond Robinson: Gynaecological Operations. 12 noon, Dr. Flett: Radiology. 3 P.M., Mr. Sinclair: Surgical Out-patients.

SATURDAY.—9 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Saunders: Medical Diseases of Children. 10.30 P.M., Mr. Maingot: Surgical Pathology.

Daily 10 A.M. to 6 P.M., Saturdays 10 A.M. to 1 P.M., In-patients and Out-patients, Operations, Special Departments.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

(Demonstration of Clinical Cases at 3.30 P.M.)

MONDAY, April 16th.—Medical: Dr. J. Browning Alexander.

TUESDAY.—Surgical (3 P.M.): Mr. Howell Evans.

WEDNESDAY.—Eye Cases: Mr. Norman B. B. Fleming.

THURSDAY.—Surgical: Mr. H. W. Carson.

FRIDAY.—Diseases of Children: Dr. C. E. Sundell.

QUEEN CHARLOTTE'S LYING-IN HOSPITAL, Marylebone-road, N.W.

THURSDAY, April 19th.—5 P.M., Mr. L. Phillips: The Scope of Cesarean Section.

UNIVERSITY OF BRISTOL POST-GRADUATE DEMONSTRATIONS (in the Medical Theatre).

THURSDAY, April 19th.—3.30 P.M., Mr. E. R. Chambers: Common Forms of Conjunctivitis.

FRIDAY (at Dorchester).—Dr. Hadfield: Diagnostic Value of Cerebro-spinal Fluid Examinations.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE LECTURES.

TUESDAY, April 17th.—4.15 P.M., Dr. J. M. W. Morison: Radiography of the Chest and its Limitations.

FRIDAY.—4.15 P.M., Mr. W. R. Douglas and Dr. J. M. W. Morison: The Diagnosis and Surgical Treatment of Lesions of the Large Intestine.

SALFORD ROYAL HOSPITAL.

THURSDAY, April 19th.—4.30 P.M., Mr. A. Smalley: Emergencies of the Ear, Nose and Throat.

Appointments.

BARRON, H. THOMPSON, M.D. Lond., M.R.C.S., L.R.C.P., has been appointed Hon. Physician in charge of the Skin Department of the Royal Waterloo Hospital for Children and Women.

ROWAN, H., M.B., B.S. Lond., Registrar to the Kensington, Fulham, and Chelsea General Hospital, S.W.

Manchester Royal Infirmary: MITCHELL, W., M.B., Ch.B. Manch., and SMITH, E. P., M.B., Ch.B. Manch., Clinical Assistants.

Vacancies.

For further information refer to the advertisement columns.

Bedford County Hospital.—H.S. and Asst. H.S. £175 and £130 respectively.

Birmingham and Midland Homœopathic Hospital and Dispensary.—Res. H.S. £175.

Bradford Royal Infirmary.—H.S. £150.

Brentwood Mental Hospital, Brentwood, Essex.—Jun. Asst. M.O. £510.

Brighton, Royal Sussex County Hospital.—H.S. £150.

Bristol General Hospital.—Hon. Asst. P.

Cancer Hospital, Fulham-road, S.W.—H.S. £100.

Carlisle Union, Fuschill Institution.—M.O. £250.

City of London Hospital for Diseases of the Chest, Victoria Park, E.—H.P. £125.

Colchester, Essex County Hospital.—H.P. £200.

Delamere Forest, Cheshire, Crossley Sanatorium.—Asst. M.O. £250.

Derby Isolation Hospital and Sanatorium.—R.M.O. £400.

Dover, Royal Victoria Hospital.—H.S. £180.

East London Hospital for Children and Dispensary for Women, Shadwell, E.—H.S. £125.

Female Lock Hospital, 283, Harrow-road, W.—Clin. Asst. £100.

Gloucestershire Royal Infirmary.—Hon. Radiologist.

Great Indian Peninsula Railway.—Dist. Surg. Rs. 700 a month.

Hôpital Français, 172, Shaftesbury-avenue, W.C.—Second Res. M.O. £100.

Hospital for Consumption and Diseases of the Chest, Brompton.—H.P. £50.

Hospital for Sick Children, Gt. Ormond-street, W.C.—Clin. Asst. M.O. in Venereal Dept. £1 ls. per visit.

Kensington Dispensary and Children's Hospital.—R.M.O. £150.

London County Mental Hospital Service.—Seventh Asst. M.O. £440.

London Homœopathic Hospital, Great Ormond-street, W.C.—Third Anæsthetist. £50.

Maidstone, Kent County Ophthalmic Hospital.—Res. Surg. O. £750.

Manchester Royal Infirmary.—H.P.'s and H.S.'s. Each £100.

Manchester, St. Mary's Hospitals for Women and Children.—H.S. £50.

Metropolitan Hospital, Kingsland-road, E.—Cas. O. and Res. Anæsth. £120. Sen. H.P. and H.S. £100. Also Asst. H.P. and H.S.

National Hospital for Diseases of the Heart, Westmoreland-street, W.—Out-patient M.O. £125.

Norwich, Norfolk and Norwich Hospital.—Cas. O. and H.S. £150.

Nottingham, Children's Hospital.—R.H.P. £150.

Plymouth, South Devon and East Cornwall Hospital.—H.S. £125.

Rotherham Hospital.—Sen. H.S. £250.

Royal Free Hospital, Gray's Inn-road, W.C.—Gynaecological Reg. £250.

Stretford Urban District Council.—M.O.H., &c. £750.

University College Hospital, Gower-street, W.C.—Res. M.O. £150.

West London Hospital, Hammersmith-road, W.C.—Hon. Med. Radiologist.

Whittingham County Mental Hospital, nr. Preston, Lancs.—Pathologist and Asst. M.O. £440 17s.

Worcester County and City Mental Hospital, Powick, near Worcester.—Jun. A.M.O. £300.

York, North Riding Mental Hospital, Clifton.—Deputy Supt. £500.

The Chief Inspector of Factories, Home Office, London, S.W., announces vacant appointments at Ryde, Isle of Wight, and at Ulverston, Lancaster.

Births, Marriages, and Deaths.

BIRTHS.

DALLIMORE.—On March 28th, at The Limes, Edgeley-road, Stockport, the wife of Dr. F. Dallimore, of a daughter.
 GOFFE.—On April 5th, at 10, High-street, Kingston-on-Thames, Edna M. Powell, M.B., B.S. Lond., D.P.H. Camb., the wife of E. G. Leopold Goffe, M.D., B.S. Lond., of a son (Michael).
 HAYNES.—On April 7th, at Brentwood, the wife of Lieut.-Colonel H. G. L. Haynes, R.A.M.C.(T.), of a son.
 McELLIGOTT.—On April 3rd, to Drs. Geraldine and E. T. McElligott, Eltham, S.E. 9—a daughter.
 MIDDLEMISS.—On March 31st, at Settle, Yorkshire, the wife of Dr. G. W. Middlemiss of a daughter.
 MILLIGAN.—On April 6th, at Woodlands-road, Ansdell, Lytham, Lancs, the wife of W. E. Milligan, M.B., B.S., of a daughter.

MARRIAGES.

BURRELL—RYAN.—On April 7th, at St. Mark's, Little Common, Sussex, Ellis Morgan Burrell, M.A., M.B., B.Ch. Cantab., of Knutsford, Cheshire, to Helen Madge, youngest daughter of Mr. John Ryan, O.B.E., and Mrs. Ryan, St. Thomas' mansions, S.E., and "Mascot," Cooden Beach.
 RAYNER—HARDING.—On April 4th, at St. James's Church, Myatt's Park, S.E., Howard Luscombe Rayner, M.B. Oxon., to Kathleen Doris, only child of Mr. and Mrs. H. J. C. Harding, of Calais-gate, Myatt's Park, S.E.
 REA—WADDELL.—On April 4th, at Shawlands U.F. Church, Glasgow, Robert Lindsay Rea, F.R.C.S., Harley-street, W., to Mary Eleanor, daughter of the late Mr. James Waddell, Glasgow.
 SHELSWELL—CRAMPTON.—On April 4th, at the Parish Church, Hampstead, Arthur Hugh Shelswell, M.R.C.S., L.R.C.P., to Eileen, only daughter of Mrs. Crampton, of Hampstead, and the late Dr. T. Hobbs Crampton.
 TAGGART—SPICKETT.—On April 7th, 1923, Hugh J. Taggart, B.A., M.B., B.Ch., D.O.M.S., of 34, Central-avenue, Hayes, Middlesex, to Frances M. Spickett, M.R.C.S., L.R.C.P., M.B., B.S., of the South-Western Hospital, Stockwell, London.

DEATHS.

MACLEAN.—On April 3rd, at Swindon House, Swindon, Wilts, after a short illness, John Campbell Maclean, M.B., C.M., in his 78th year.
 YEATS.—On April 4th, at Oakhurst, Romiley, Cheshire, William Yeats, M.D., M.B., C.M., &c. (late of Manchester), aged 74.
N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

THE PRINCIPLES AND PRACTICE OF HEALTH LEGISLATION.

Abridged from a Public Lecture delivered under the auspices of the Chadwick Trustees, in the Inner Temple Hall, on March 12th, 1923.

BY CHARLES PORTER, M.D., B.Sc., M.R.C.P. EDIN.,

OF THE MIDDLE TEMPLE, BARRISTER-AT-LAW: MEDICAL OFFICER OF HEALTH, METROPOLITAN BOROUGH OF ST. MARYLEBONE.

LOOKING at health legislation administratively it is possible to see it as something other than law pure and simple. Dealing with it we are in fact not dealing with *health law* but with the *laws of health*, which have as their sanction not the fines and imprisonment that the law talks of and the courts may impose, but injury to health, sickness, disease, and even death, penalties that the law does not mention, but that a court higher than the highest of our courts may exact.

The measures containing these rules are very numerous: not because the rules themselves are numerous, but because they have to be applied in a variety of ways to a number of different matters. The bulk of these measures are comparatively recent; few of them go back much beyond 1875—rather less than 50 years ago—and most of them had their origin in Acts of Parliament not yet 100 years old. This does not mean that nothing in the way of health legislation was thought of or promoted and passed before that time. Nor does it mean that hygiene is an entirely new subject and that the earlier doctors or governments had not thought of preventing disease or of laying down laws of health. All it does mean is that it was not considered possible to apply health rules for the benefit of a mass of individuals, since local government in the communities was not sufficiently organised and there was no one to see that the rules were adopted and applied.

Principle of a Central Organisation.

In this country the need for an organisation in connexion with the application of the laws of health and as a preliminary thereto, was one of the first things to be recognised when the health conscience awoke and what may be called the real era of health legislation began. This may be regarded as the main principle underlying the whole of our health legislation, and of its soundness there can be no question. That it was adopted and adhered to is, to my mind, one of the reasons why our health scheme is superior to that of any other nation in the world. Like so much that is good in the sphere of public health, we owe thanks for it to Chadwick, a social reformer, and to Sir John Simon, the first real practitioner of preventive medicine this country ever saw. These two were the architects, and to a large extent the builders, of the system now in operation.

Having recognised the first broad principle—viz., the necessity for setting up an organisation, and, more important still, having brought others to recognise it, how did Chadwick and those with him proceed to establish it? The recognition of other principles was involved, the chief of these being that the need for organisation would not be properly met unless such as was set up was in intimate contact with the place where the health legislation was to operate. To have this properly grasped was a task of considerable difficulty, but as may be gathered from the legislation itself it was ultimately accepted. For proof of this it is necessary only to turn to the Public Health Act, 1848, which was the first Act bearing this name to be passed. Described as an "Act for Promoting the Public Health" its objects were set out in the preamble as follows:—

"Whereas further and more effectual Provision ought to be made for improving the sanitary Condition of Towns and populous Places in England and Wales, and it is expedient that the supply of water to such Towns and Places, and the sewerage, drainage, cleansing, and paving thereof, should, as far as practicable, be placed under one and the same local management and control, subject to such general supervision, as is herein-after provided: Be it therefore enacted"—and so on.

In this it will be noted that, in addition to referring to local management and control, there is reference to a need for "general supervision."

General and Local Boards of Health.

The body charged with this general supervision was to be known as the "General Board of Health" and was to consist of the First Commissioner of Woods and Forests and two other persons appointed by Royal Warrant. This body had power to appoint various officers and servants and "superintending inspectors"; its existence, however, was limited to five years. As a matter of fact it lasted about

ten years, but speaking generally it does not appear to have been liked. The whole Act, indeed, encountered a great deal of opposition, both before and after it was passed, some of those who opposed it doing so from dislike of the General Board of Health; others mainly because they objected to the provisions as to the setting up of local boards of health which involved, under certain conditions, the imposition of the body upon the locality and also, if they happened to be property owners, because they feared interference by the officers whom the Board was given power to appoint. The ostensible reason for objecting to the General Board of Health was that in regard to it there was a violation of principle in that it was not a representative body but consisted or might consist of paid officials. The real reason, however, was—as I think—that it displaced the Privy Council, which regarded itself as a sort of central health body, particularly in relation to epidemic diseases in respect of which it issued orders from time to time.

During the years the 1848 Act was in operation and the General Board of Health in existence a great amount of good was done and many local boards were set up. In spite of this, however, it disappeared, and the Privy Council once more became the central body. The local boards continued for some time longer, though they appear to have been in some places at loggerheads with some of the other bodies in their own area.

Early Health Officers.

One of the best things done by the Privy Council after they resumed the reins was the appointment of Dr., afterwards Sir John, Simon as medical officer. To take up this appointment Simon dropped that of medical officer of health of the City of London, a post created in 1848, of which he was the first holder. He was not, however, the first medical officer of health. Actually the first to hold this office in the country was Dr. Duncan, who was made medical officer of health of Liverpool in 1847 under a local Act of Parliament. The example set by Liverpool, and followed by the City of London, led to the appointment of medical officers of health in several other districts, and by 1856, in which year there were no fewer than 230 districts with a local board of health, each having power to make an appointment, there was quite a number of such officers.

In addition to making provision for the appointment of a medical officer of health, the 1848 Act provided for the appointment of other officers, the most important from our point of view being an inspector. To this officer there was given, in the first instance, the title of Inspector of Nuisances, and later of Sanitary Inspector, this being afterwards changed back to Inspector of Nuisances, and finally, we may hope, in the Public Health (Officers) Act, 1921, once again to Sanitary Inspector. In the 1848 Act, and to an extent also in other Acts to be mentioned later, the idea appeared to be that the officer most necessary was the inspector, the medical officer of health being brought in later for infectious disease purposes and to support the inspector in connexion with nuisances that might be dangerous to health, and something more than mere nuisances and eyesores. If this was the idea it did not quite work out, for in time the relative positions completely changed, the medical aspect of the work becoming more prominent, and the medically qualified taking the lead of the nuisance and sanitation officer as chief executive health officer.

The definite recognition and adoption of this principle in this country was made in the Public Health Act, 1875, in which one of the earliest duties imposed upon the local health authorities created by that Act was the appointment of a medical officer of health. Before this Act came into operation, however, many changes took place, while in the Act itself many new principles affecting health legislation and practice were developed and established. One of the most noteworthy happenings had been the relinquishment by the Privy Council of its position as central health body. When it gave up there was no return to the General Board of Health, its career having ended finally with the disappearance of the 1848 Act. The local boards of health had also suffered, as the view that health work was one of the ordinary activities of the district councils and not of the board of guardians or any ad hoc body came to be more widely accepted.

The Local Government Board.

To take the place of the General Board of Health and the Privy Council there was set up by a special Act of Parliament a body known as the Local Government Board, and as central authority for the bulk of health purposes it continued to function from the day of its formation until 1919 when, as everybody knows, the Ministry of Health was created, and unwept and unsung the old Board passed away, presumably for ever. By the time the Local Government Board was created Simon was practically ready to declare his task completed, by having the principle definitely recognised that in public health the function of a central body should be practically entirely supervisory and that of the local bodies executive. Himself a central body

officer, he never ceased to enunciate this principle, and throughout the whole time he was acting as medical officer of the Privy Council, as he tells us himself, he was using every effort and opportunity to work up the local authorities not only of the ports (important because of cholera in the prevention of which he was particularly concerned) but elsewhere, to establish a complete health and preventive unit within their own area. In Simon's mind there is no doubt that what bulked most largely was preventive work, and what he really wanted to see was a complete system of dealing with infectious diseases, including hospital accommodation.

Chadwick, it always appears to me took a wider as well as a more humanitarian view, desiring to see conditions improved not only because he felt sure that by improving them he was clearing the breeding grounds of disease, but because he believed that the people would be bettered in health generally and in all other ways if their surroundings were improved. In a word, it was social improvement Chadwick desired to see, and it was because of this and because of the vast influence of Chadwick that our health legislation, that of early times certainly, and to an extent that of to-day also, is as much social as it is medical.

Legislation and Environmental Conditions.

The occurrence of cholera outbreaks and threats of others had heightened the demand amongst the people for provisions relating to health and sanitation. The provisions wanted were those most likely to prove effective, and as there appeared to be reason in both sets—those dealing with environmental and social conditions and those aimed more directly at disease prevention—it was eventually decided to have both.

Amongst environmental conditions those proposed to be dealt with included: (a) Sewerage and drainage; (b) water-supply; (c) nuisances; (d) offensive trades; (e) housing; (f) food protection.

Curiously, little absolutely new legislation was required in order to make provision for most of these matters. As already stated, in the 1848 Public Health Act, though its main intention was to provide for health organisation, a number of sections relating to sanitary matters were given a place. These dealt with sewerage and drainage, making it the duty of the local board set up under the Act to take over existing sewers and look after them and provide new ones; and in regard to drainage forbidding the erection of houses without water, drains, and sanitary conveniences. The duty of cleansing and scavenging was also imposed upon the board who were required further to see to the provision of a water-supply. In regard to general matters, power was given to call for the cleansing and purification of houses, for the registration of common lodging-houses, and to forbid the occupation of cellar dwellings. Provision was also made for controlling slaughter-houses and offensive trades.

Local Health Legislation.

In a number of districts steps had already been taken to ensure that environmental conditions in respect of at least the matters mentioned should be improved. Power to do so had in some cases been obtained under special "Local Acts," the cost of which had been borne by the areas to which they were applied. Parliament, indeed, had even gone so far as to provide "Model Acts" for the use of districts desirous of bringing about improvements and promoting Acts for themselves. The chief of the model Acts was that known as the Towns Improvement Clauses Act passed in 1847. In this there were contained a large number of sanitary provisions, of which several districts had availed themselves.

The principle of allowing and even encouraging local authorities to promote health legislation on their own account is still practised and recognised. Indeed, quite a number of the provisions now included in legislation applicable uniformly over the country was first tried in a small way in one area under a measure locally operative only. Notification of infectious diseases, for example, was introduced first locally in Huddersfield, and tuberculosis came to be added to the list of notifiable diseases only after Sheffield had obtained provisions calling for notification in that town. New provisions of this kind, if satisfactory, rarely remain limited in their application.

Nuisance and Disease Prevention.

In 1848, in addition to the Public Health Act, there was passed a measure of considerable importance—viz., the Nuisances Removal and Diseases Prevention Act, 1848. So far as nuisances were concerned this Act contained, in addition to a list of conditions that were to be regarded as nuisances, provisions relating to the methods to be adopted with a view to enforcing remedies and preventing recurrence. As to infectious disease, the chief provisions were those that gave power to the Privy Council to issue orders making the part of the Act relating to infectious diseases operative in certain areas and to the General Board of Health to issue directions and regulations as to the steps to be taken with a view to prevention. The Act, it may be noted, was very

cumbersome, operating only in districts to which it was applied. In 1849 it was amended and in 1855 it was transformed into two Acts, one relating to nuisances and the other to disease prevention. With perfect safety, indeed, it may be said that provisions very similar to those contained in that Act are still in operation, most of them having been incorporated in the Public Health Act, 1875, in which all existing health Acts were consolidated. This Act is still in operation, supplying the power under which the bulk of public health work done in England is carried out.

Special Acts.

Housing.—Acts dealing with other special subjects were passed at or about the same time, amongst which reference may be made to some relating to housing questions. The Common Lodging Houses Act of 1851 grew out of the 1848 Act itself and continued in operation for a number of years in places in which the 1848 Act applied. Later, its provisions were incorporated in the 1875 Public Health Act, later again to be extended by a number of fresh provisions in the Public Health Acts (Amendment) Act, 1907. Further, with regard to housing, it may be noted that in 1851 there was passed what may be taken to be the first Housing Act. This bore the title of the Labouring Classes Lodging Houses Act, and was followed by the Labouring Classes Dwelling Houses Act of 1866 and 1867. In 1868 the Artizans and Labourers Dwellings Act appeared, and in 1879 the Artizans and Labourers Dwellings Improvement Act. The first Housing of the Working Classes Act proper was passed in 1885, the first including town planning provision in 1909.

Generally speaking, the principle of these Acts appeared to be to induce and encourage local authorities to undertake the provision of housing accommodation themselves. In the later period they were strengthened by the offer of financial assistance out of national funds, and by the grant of powers to acquire land and premises compulsorily. Power was also given to interfere with existing property, altering it or requiring the owners to alter it with a view to encouraging overcrowding and disproving the view that it is impossible to squeeze a quart into a pint pot. In the earlier Acts there was no reference at all to overcrowding, and it was not till later Health Acts were passed that power to deal with the condition was given, and then only as a nuisance.

Water-supply.—In relation to water supply special legislation also became necessary and was in fact provided. Under the Public Health Act, 1848, it was made the duty of the local boards of health to take steps with a view to providing a proper supply for their district and in due course the provisions relating to this subject were incorporated in the Public Health Act, 1875, and are still in operation.

Food.—Provisions in public health Acts and sanitary Acts generally soon proved to be inadequate in regard to food-supply. A large amount of special legislation has been passed, some relating to foods generally, others to definite articles. Since 1875 there has been more or less of a steady flow of food legislation. Between that date and 1897 several Food and Drugs Acts were passed, some with the object of clearing up legal difficulties, others to make provision with regard to special substances.

Milk.—It was not till just about the outbreak of war that any real attempt was made to legislate with regard to other than the chemical aspects of milk. That it might be a vehicle for the conveyance of infection had been recognised in the Infectious Disease (Prevention) Act, 1899. It is also a fact that in 1912, by means of regulations, the practice of doctoring it by the addition of preservatives was forbidden. No real legislation, however, existed in which it was written down as a possible factor in the occurrence of tuberculosis amongst children; or described as a substance that must be produced and sold only in a clean condition. An Act bearing to some extent on these matters—The Milk and Dairies Act—was passed in 1914, but for one reason or other its operation has been postponed from time to time since then, and it is still in a state of suspended animation. By way of a *pis aller*, in 1922, what was called a Milk and Dairies (Amendment) Act, was passed, and this is now in operation.

Disease Prevention.—The objective of all health legislation is disease prevention even though the provisions only aim at improvement in environmental conditions. The very first disease prevention provisions were actually wedded to those relating to nuisance removal in the Nuisances Removal and Disease Prevention Act of 1848, the placing of nuisance removal first being perhaps not without significance. At the time when they were separated from nuisance removal in 1855, a great fight was raging over the question of quarantine. Simon eventually succeeding in getting rid of quarantine and substituting for it a system of examining crews and passengers on board ships, especially those from infected ports; isolation at the port of all found or suspected to be suffering from particular diseases, and supervision of all others, who were allowed to leave on giving their names and the address in the place to which they were proceeding.

It was in order that the supervision in any place within the kingdom might be complete that Simon desired to have a proper and uniform local health organisation in all areas, with machinery for dealing with disease, including hospital accommodation. It was as a result of his efforts, no doubt, that in the Public Health Act, 1875, in addition to the provisions taken from the Disease Prevention Act, there were introduced others relating to hospitals, removal and isolation of infected persons, and cleansing and disinfection of premises, both as a safeguard against the outbreak of disease and against spread of infection from an infected house, from an infected person, and from the contacts with such a person. The provisions with regard to disease prevention have been very little altered as time has gone on. In a word, it might be claimed that the principles of disease prevention were enunciated by Chadwick and Simon, and that they have never been departed from since.

Personal Hygiene and Preventive Medicine.

It is the tendency of public health in the present day to attempt to make out that everything possible has been done so far as environmental conditions are concerned, and that the time for concentrating on direct effort for the benefit of the individual, for seeing what can be done for and through him personally, has arrived.

There is a curious tendency to believe that Chadwick and Simon and all these other great ones (if, indeed, the bulk of health officials and workers ever think of them and their work at all) gave no consideration whatever to the individual. For my part, and having regard to the opinion I have formed of these men, I find it impossible to believe that with their keen sight they could have failed to recognise that personal hygiene, welfare work, and preventive medicine in their very widest sense possessed tremendous importance and must somehow or other and sometime or other be provided for. They recognised also, no doubt, the difficulty and hopelessness of tackling the individual in their own day, on account of the ignorance of the people; only a really well-informed people can be made to make themselves a healthy people.

It must have been obvious to Chadwick and Simon that the proper course was to concentrate upon matters urgently calling for attention—viz., such social and environmental conditions as could be improved without assistance from, and even in spite of, the people, leaving personal hygiene and preventive medicine in its narrower sense of direct action in relation to the individual for the future and for the health officers and enthusiasts who were to come after them. And to-day what are we doing more than merely extending the practice then introduced?

Welfare of Mothers and Children.

So far as school-children are concerned the important Acts are the Education (Administrative Provisions) Act, 1907, and the Education Act, 1918.

As regards infants the measures to be noted are those requiring notification of births to the medical officer of health, the first, which was adopted, passed in 1907, the second making the requirement generally applicable which came into operation in 1915. These Acts were really preliminary to the Maternity and Child Welfare Act, 1918, the most important of the group, since it provided for the setting up of committees to whom power to do practically anything likely to benefit infants and their mothers was given. The Acts relating to midwives and their practice may safely also be counted in with those designed to assist certain sections of the population though their efforts are less directly produced.

A Guide to Healthy Living.

All health legislation is based on principle and consists exclusively of principles. The things it directs and orders all of us to do or to have done or to see done are just those things that an individual of principle would regard as right. As a whole, as I have already stated, sanitary law is not really law but a series of rules; it is more, it is a guide to right living, healthy living for ourselves and for each other.

We have much to be thankful for, in that we possess incomparably the best health organisation in the world and a health code which, though it may have faults, such as that it is complicated, makeshift in parts, and full of compromises, is nevertheless reasonable, workable, and free from stunts. In the main it conforms to the basic principle underlying all or most of our legislation in that it represents the will of the people and not the views of cranks and experts. All of it practically has been considered and reconsidered, drafted and redrafted, pruned and criticised, tried and tested, by numbers of persons and bodies before it is put into general operation. But most important of all, our health laws are something more than printed words; few of them are dead letters, most of them can be and are worked, and none of them are "imposed." As a result of their working and the application of their underlying principles, have come, amongst other benefits, a reduction

of the death-rate amongst infants from well over 100 deaths per 1000 births to under 80 in the course of 12 or 15 years, and such an improvement in the health of the people generally that the average age at death has been considerably postponed, and the average death-rate in any one year reduced from over 20 per 1000 in the "seventies" to just over 12, the figure at which it stands to-day.

A REVISED SYLLABUS IN MATERIA MEDICA AND PHARMACOLOGY.

A REVISED synopsis of the examination in Pharmacology, Practical Pharmacy, and Materia Medica, which has been drawn up by the examiners to the Conjoint Board of the English Royal Colleges (Dr. A. E. Russell, Dr. E. A. Cockayne, Dr. P. Hamill, Dr. A. J. Clark, and Dr. W. E. Dixon) will come into force at the examination in October next. Candidates will be required to recognise the drugs and preparations in Schedule A. They will also be required to know the constitution and the chemical and physical properties of the drugs in Schedule B, in so far as these properties are of practical importance in medicine. Finally, they will be required to show a competent knowledge of the pharmacological action and doses of the drugs in Schedule B, and of the preparations of these drugs. Experimental evidence as to the mode of action of drugs, therapeutics, pharmacy, and pharmaceutical details as to the modes of preparation of drugs will form no part of the examination.

Schedule A.—Mercury subchloride, mercury with chalk, arsenious anhydride, arsenical solution, potassium permanganate, ferrous sulphate, iron and ammonium citrate, iodine, ether, chloroform, paraldehyde, amyl nitrite, aromatic spirit of ammonia, chloral hydrate, carbolic acid, camphor, liniment of camphor, quinine sulphate, opium, ergot, oil of turpentine, creosote, compound senna mixture.

Schedule B.—Ammonium carbonate, ammonium chloride, ammonium acetate; potassium carbonate, potassium bicarbonate, potassium citrate; sodium sulphate, acid sodium phosphate; magnesium sulphate; calcium carbonate; silver nitrate; copper sulphate; zinc sulphate; lead acetate; alum; bismuth carbonate, bismuth oxychloride; barium sulphate; sodium hypochlorite, chloramine-T; iron, iron sulphate, iron perchloride, iron and ammonium citrate; potassium permanganate, hydrogen, peroxide; mercury, mercury subchloride, mercuric chloride; arsenious anhydride; arsenobenzol, neoarsenobenzol; antimony tartrate; potassium bromide, potassium iodide, iodine, iodoform; hydrochloric acid, citric acid, caustic potash; gentian, calumba senega; croton oil, castor oil, phenolphthalein, cascara sagrada, aloes, senna, rhubarb, jalap, colocynth, sulphur, liquid paraffin; tannic acid, kino; male fern, santalin, pelletierine tannate, oil of chenopodium; cod-liver oil, dried thyroid, pituitary extract, adrenalin hydrochloride; colchicum; digitalis, strophanthus, squills; caffeine, theobromine, theocine; amyl nitrite, sodium nitrite, nitroglycerine; ipecacuanha, emetine; nux vomica, strychnine; opium, morphine, codeine, apomorphine; belladonna, atropine, hyoscyne, homatropine; physostigmine; cocaine, ethocaine (novocaine); cinchona bark, quinine; rectified spirit, ether, chloroform, ethyl chloride, nitrous oxide; chloral hydrate, paraldehyde, barbitone; hexamine, oil of copaiba; ergot; carbolic acid, cresol, creosote; phenacetin, sodium salicylate, salol, acetylsalicylic acid; formaldehyde solution, paraform, menthol, camphor, thymol, oil of turpentine, cantharidin, mustard leaf.

PLAGUE PREVENTION IN JAVA.

AN illustration of the best form of publicity in the promotion of public hygiene is supplied by *Health*, a new monthly journal issued by the Commonwealth of Australia Department of Health, of which the second number (February, 1923) is concerned chiefly with plague prevention. Dr. J. S. C. Elkington, the chief quarantine officer of the North-Eastern division of the Commonwealth, contributes a graphic account of plague control in Java. In this tropical island the problem has been tackled by the Dutch Civil Medical Service with common sense and with clearness of vision, not hindered by the many difficulties of caste or religion. Investigation showed that spread from man to man was negligible as a factor, and the problem was reduced to the classical one of breaking the flea connexion between man and the very few species of rats which serve as reservoirs for human infection. Three species of rats—an "unholy trinity"—played this rôle, the most important one being the *Mus rattus griseiventis*, which is a strictly house rat, and cannot live a feral life in competition with the other prevailing species of rats. The problem, therefore, was one of rat-proofing houses and keeping them rat-proof. The means by which grass roofs were replaced by tiles and by which bamboo rafters were rendered rat-proof are given fully, and they are important as showing the practicability of the problems. The results were soon shown. As the Plague Prevention Service moved on plague disappeared in its track. Nothing was left to chance, and village by village the island is being rebuilt. In Dr. Elkington's words: "The Dutch authorities admit that it may take a long time and a great deal of money, but they refuse absolutely to accept plague as an ordinary feature of their colonial landscape in the twentieth century."

INSULIN: A SIMPLE EXPLANATION.

WE have received from the Therapeutic Foods Company (Energen Works, Willesden, London, N.W.10) a small pamphlet outlining the rationale of the employment of insulin in the treatment of diabetes. The leading facts are well set out, as is the reasoning which has led up to the various steps of research and experiment. Proper emphasis is also laid upon the limits of our existing knowledge, the warning being distinctly given that there is no proof as yet that insulin is definitely a cure for diabetes. Its employment will not eliminate the necessity for dietary regulation.

PUBLIC HEALTH IN SEYCHELLES.

AT the census of April 24th, 1921, the population of Seychelles was returned at 24,523 (11,974 males and 12,549 females), showing an increase of 1832 on the figures of 1911. The birth-rate for 1921 was 28.91 and the death-rate 15.98 per 1000. An epidemic of whooping-cough caused many deaths among young children. There was also a slight influenza epidemic. In spite of its proximity to the equator, Seychelles is reputed to be one of the most healthy of the British possessions within the tropics. Its climate is mild and equable. The maximum shade temperature rarely exceeds 86° F., while at night the temperature seldom drops below 74°. Thus, during the whole year the temperature only varies over a range of about 12°. The rainfall averages about 90 inches.

DENTAL RESEARCH: A SUGGESTION TO DENTISTS.

AT the close of his admirable lecture on the Diseases of the Periodontal Tissues, reported in full in the *British Dental Journal* for April 2nd, Mr. J. Howard Mummery drew attention to the great desirability of increased activity in research among the members of the dental profession. There are, he said, so many difficult questions in the pathology of the teeth and the surrounding structures that call for further investigation and so few workers in the field; and he went on to make the practical suggestion that everyone in practice should keep at hand a bottle of 10 per cent. formal and place such specimens immediately in the solution for investigation by those who are able to give them the necessary time and attention. Many valuable examples would not then be lost to science, as they now are.

THE AXE FOR CRIPPLES.

THE Board of Education has recently issued a circular (No. 1297) to local education authorities and to managers of special schools, containing preliminary proposals for reduction of staff in special schools. Mr. Morgan Jones questioned the President of the Board in the House of Commons on the effect of these proposals. The drastic economy suggested will in fact limit the practical work in the majority of these schools, so that it will become little more than a phantom. The teaching staff for crippled, blind, and deaf children cannot be strictly rationed without negating the whole conception on which this special education has been built up. We hope that the full provision of educational facilities for afflicted children will not be prejudiced by any short-sighted parsimony.

THE FITNESS OF FOOD-HANDLERS.

Kansas City, as we noted recently (*THE LANCET*, 1922, ii., 679), has been particularly active in seeing that its food is not subjected to gross risk in handling by diseased persons. In Texas the court of criminal appeal has now held valid an ordinance of the city of Dallas which provides that any person working in a "food establishment" must have a certificate stating that he has been examined by a "reputable physician" and found to be free from any communicable disease. This ordinance made proprietors of food establishments subject to medical examination, and the appellant whose appeal against a conviction, made in the form of an application for a writ of habeas corpus, was dismissed, was the proprietor of a meat market, and had been convicted of having worked in his own establishment without a health certificate. The equivalent in this country to an appeal of such a kind would be against a conviction under a by-law of a municipal authority, on the ground that it was *ultra vires*. The city of Dallas may be congratulated upon a very useful regulation, which might be studied and adapted far beyond its boundaries. In this country we have only to observe the conditions which surround the delivery of bread and milk to the consumer in order to appreciate the room there is for improvement in our precautions for the protection of the public health. The ordinance made by the city of Dallas, and upheld by its court, for "food establishments" apparently would provide against persons being carriers of disease who serve in any capacity in the markets where food is prepared and distributed, and in places where it is consumed, such as hotels and restaurants.

A Lecture

ON THE

PSYCHOLOGY OF COURAGE.

*Delivered at the Royal Air Force Staff College on
March 1st, 1923,*

By J. L. BIRLEY, C.B.E., M.D. OXF.,

F.R.C.P. LOND.,

CONSULTING PHYSICIAN TO THE ROYAL AIR FORCE, ETC.

THERE are very real and proper reasons for hesitating to talk of courage to an assembly such as this, and the first is that in the good old days, not so long ago perhaps, both the lecture and the lecturer would have been officially banned. It would have been tacitly assumed that courage was inherent in every soldier because he was a soldier, and that under no imaginable circumstances could any soldier lack this quality. It would have been realised that any inquiry into courage must inevitably involve an inquiry into fear, a most reprehensible and dangerous subject for discussion in a school of military instruction. Moreover, seeing that courage is part of the official equipment of every soldier, that it rains upon him as manna rained upon the Israelites in the Wilderness, what possible benefit could accrue from an analysis of this heaven-sent virtue, even supposing that any analysis was possible?

Secondly, one instinctively hesitates to trespass on ground which has been consecrated, and that so recently, by so many great deeds and immortalised by some of the greatest writings in history. But it is as little my intention as it is within my power to declaim the virtues of courage or indulge in panegyrics. My object is quite other than that, and instead of eulogising the manifestations of courage I shall attempt to investigate its origin and purpose, together with the factors which modify it in one direction or another, not forgetting that this quality is not wholly confined to man, still less to the male sex, and that in man, in whom it reaches its highest pinnacle, there is the courage we call moral no less conspicuous and no less instructive than the courage we call physical.

My third ground for hesitation centres round the word psychology, a subject which has occupied the public stage very considerably of late and that, too, in a not very attractive way. The advance of science has always been along the path of hard work, and its progress has never yet been assisted by public parade or advertisement, factors which more often than not have tended to bring the thing studied into confusion, or even disrepute. We have evidence of this in the pseudo-scientific craving evinced for psychological theories in recent years, and we are now witnesses of the unedifying spectacle of an indiscriminating public flocking from Freud to Mrs. Eddy, from Christ to Coué, with an impartiality that might be refreshing were it not pathetic. We are here to-day, however, to study the psychology of the natural rather than that of the morbid, and seeing that this is a lay assembly I shall be able to dispense with the luxuriant language of modern psycho-pathology and have recourse only to words that we can all understand. You must not expect me to indulge in any metaphysical abstractions, for towards these I feel much as Gibbon did when he alluded to "the science, I should say the language, of metaphysics."

THE MEANING OF PSYCHOLOGY.

What, then, do we mean by psychology? We mean the study of the mind as part of the organism; and just as we cannot study the bodily organism without considering the stages through which it has been evolved, so is it unwise and misleading to study the mind of man apart from his history. Similarly the study of individual behaviour is meaningless and empty unless we also study environment, and the

environment of man is essentially man. In other words, the behaviour of any organism—and courage is nothing more than a quality of mind, however noble, associated with certain lines of behaviour—is conditioned largely by evolutionary factors. The only proper method, therefore, for pursuing the study of the mind is the comparative one, and once we realise that psychology is merely a branch of the larger science of biology we shall feel confident that we are on safe ground. I accordingly approach the psychology of courage from the point of view that "Nature has made up her mind that what cannot defend itself shall not be defended."¹ Now the idea that courage has been acquired along evolutionary lines, and that is the argument I propose to elaborate, might at first sight seem a little cold and forbidding to those who, content to indulge in a purely intellectualistic psychology, prefer to regard this noble quality as the particular and cherished attribute of man alone. But our bodies have been evolved through processes extending over millions of years, and have they lost anything of dignity or beauty in their evolution? Does its embryonic origin and intra-uterine development detract from the wonder of the infant or its beginnings in a seed from that of the flower? On the contrary, knowledge enhances wonder.

Again, just as it is a mistake to investigate the activities of man or of any other animal apart from their histories, so is it unsound to divorce the study of the activities of the mind from those of the body, for between body and mind there is an intimate co-partnership both in health and disease. Mental processes, particularly those associated with affect or emotion, are invariably accompanied by changes in the bodily state. It is not labouring the commonplace to draw attention to this fact; rather is it more correct to say that its universal recognition is responsible for the failure to realise its significance. Thus we blush with shame, cry with sorrow, when afraid we sweat and tremble, and when amused we smile. The stage, and particularly the cinema, actor depends for his success on the skill with which he can reproduce the physical manifestations of the emotions he is supposed to feel. Conversely it is well known that conditions originating within the body effect alterations in consciousness: hunger, for example, is associated with a particular type of contraction of the muscular wall of the stomach, and these contractions are terminated by the ingestion of food. Similarly, pain is accompanied by the inhibition or cessation of the secretion of gastric juice. Arguing on these lines it has even been suggested² that the source of behaviour is to be found in the periphery, or, to put it colloquially, the stimulus which compels the organism to such behaviour as shall satisfy its cravings arises in the organs of the body rather than in the higher nervous centres, while the latter merely serve to coördinate and integrate these various cravings of bodily origin. I mention this somewhat fantastic theory in passing in order to impress upon you the inter-dependence of mind and body.

COURAGE IN LITERATURE.

Proceeding now to examine the subject of courage as it appears in literature, certain features demand our attention.

The first is that courage is applauded for what it is, as an entity, and little if any attempt is made to investigate the elements of which it is compounded or the motives which underlie it. The element of fear, for instance, is either completely ignored or glossed over, and courage is left in splendid isolation, the perfect quality, heaven-sent, and "people forgive everything to it."¹

Secondly, perhaps because it lends itself more readily to treatment, or perhaps because it is more intelligible, the courage of the individual rather than that of the mass takes pride of place in the literature of all ages and nations.

Thirdly, it is interesting to observe that the actual words by which this quality is described have not always had the same meaning.³ This is not the case

with the word "courage," which although used by Chaucer as synonymous with "heart" (from the Latin "cor") as the seat of feeling, rapidly became identified with spirit, liveliness, vigour, and finally with readiness to face danger. With the word "bravery," however, it is different; derived from a French or Spanish source, it originally denoted the action of braving or acting the bravo—i.e., daring, defiance, boasting, swaggering, bravado—while the noun "brave" indicated a bully or hired assassin. Only later did it come to mean courage, valour, fortitude, and even now it sometimes implies show, ostentation, splendour, or finery, as, for example, in a description of a London crowd in the park, "Tens of thousands in all their Sunday bravery." So again the adjective "bold," an old Saxon word, was and still is used to indicate not only the stout-hearted, courageous, and fearless, but also the audacious, presumptuous, the opposite of modest, as in the phrase "a bold young woman," or "bold-face," meaning an impudent person. Bacon used "boldness" as synonymous both with impudence and hot-headedness; "the right use of bold persons," he says, "is that they never command in chief, but be seconds and under the direction of others; for in counsel it is good to see dangers, and in execution not to see them except they be very great."⁴

Fourthly, the most divergent views are current regarding the type of individual who is courageous, and the extremely varied incidence of courage has often been a matter for surprise. During and since the war, for instance, people have busied themselves with such intangible problems as to whether colliers are braver than clerks or artisans than farmers, problems which have proved unexpectedly difficult to solve. Captain John Brown, the hero of Kansas, held the belief that the quiet peaceable man makes the best soldier; "as for the bullying drunkards of which armies are usually made up, he thought cholera, small-pox, and consumption as valuable recruits."¹

"'Tis still observed that men most valiant are
Who are most modest ere they came to War."

On the other hand, we have the opinion of one⁵ who, writing about the recent war, remarks, "One of the things that astonished me most was to find out the types of men who were most brave; the drunkards, the rakes, and the dandies were a long way first. The high-minded, religious people of strong principles were often good diers, but not often good fighters. The orderly, well-disciplined, obedient types were more often than not quite useless in the face of the enemy." He goes on to say how he was discussing the psychology of bravery with Sem, the French caricaturist, and "was telling him how extremely gallant were the dandies and the fops, and he made this wise answer, 'Après tout, le courage—c'est une élégance.'" In the course of this lecture I hope we shall find some means of reconciling such opposite opinions, and shall come to understand that courage is something much more than "une élégance."

DIFFERENT FORMS OF COURAGE.

It is customary to recognise certain forms of courage. First and foremost is the pure and sublime courage, its beauty lauded in prose and sung in verse throughout history. "the endowment of elevated characters,"¹ a virtue regarded with reverence, awe, and envy, the sole prerogative of man. Such courage is eminently attractive from its being effortless and natural. It is characterised by equanimity and outward calm, and neither fear nor anger approach it; it is quiet, unruffled. Its tranquillity contrasts strangely with the power and energy it wields. "The immense esteem in which it is held proves it to be rare."² And at that we may leave it, not forgetting that women as well as men have contributed in no small measure to its irresistible appeal—Joan of Arc, Florence Nightingale. Psychologically this form of courage represents the complete success of the process by which fear is kept out of consciousness; this process, which is wholly unconscious, is called suppression.

Secondly, there is courage in spite of the presence of fear. Unlike "sublime courage" this form has received but scant attention in literature, and yet most of us would allow it to be one of our commonest modes of reaction to danger. The almost pointed way in which fear is ignored by the essayist suggests a disinclination to face facts which appear unpalatable and reflects a habit of mind both of writer and reader which prefers to arrive at comfortable conclusions rather than the truth. This method of dealing with unwelcome experience by professing to ignore it is, I believe, far less general than it used to be, and people nowadays are inclined to think with more honesty and less pretence. This advance has been greatly facilitated by the war, and especially is this the case with our views concerning courage. It is true that no one quite likes to admit feeling afraid, and such slang expressions as "wind up," "cold feet," and "needle," which enable us to talk freely about fear without actually naming it, are evidence of this natural disinclination. It was recently my privilege to listen to the evidence given by many eminently brave men before the War Office Committee on (so-called) Shell Shock; they all knew what fear was, and few of us would hesitate to admit in the words of one of them, and incidentally, one of you, that "All men know fear; some conceal it better than others, a few bury it out of sight, but it is there all the same."³

"If you can force your heart and nerve and sinew
To serve your turn long after they are gone,
And so hold on when there is nothing in you
Except the Will which says to them: 'Hold on!'"⁴

The second form of courage occurs, then, in the presence of fear, but fear is repressed sufficiently to allow of the dangerous situation being adequately dealt with; the process of repression is, however, not unconscious, as in the first type of courage, but conscious, sometimes acutely conscious.⁵

A third aspect of courage is recognised—namely, courage for the sake of display or notoriety, and it is in connexion with this form of courage in particular that the various meanings of the words "boldness" and "bravery" have their chief interest. From the psychological point of view this aspect of courage is of the greatest importance, for it implies that the individual is prepared to dare dangers in order to secure some advantage pleasing to himself. Now assuming that in the majority of individuals the presence of danger is normally associated with the presence of fear of some degree, we have here to deal with a case in which the emotion of fear is masked or actually replaced by another emotion—namely, the pleasurable emotion associated with personal advancement, gain, or success, which the individual anticipates. Now a much commoner mode of reaction to danger, both in animals and man, is by aggression, in which the emotion of fear is replaced by the emotion of anger; we "see red." Accordingly, I propose to call this third form of courage, whether it be the courage of anger or the courage of display, the "courage of substitution." It illustrates the complexity of the mechanisms at man's disposal, whereby threatening situations may be met, and, further, it constitutes a means whereby, when the danger is not averted, its consequences—namely, physical or mental pain—may be mitigated or completely suppressed by the substitution of some emotional state of great intensity. For example, a hack on the shin at football is often not felt until the game is over. Similarly, fervour, enthusiasm for a cause, especially religious enthusiasm, have inspired some of the most famous acts of courageous devotion, such as that of "the poor Puritan, Antony Parsons, who at the stake tied straw on his head when the fire approached him, and said 'This is God's hat.'"¹

The last form of courage which is generally recognised is what one may call negative courage, or, if you prefer it, the courage of ignorance. Here it is implied that fear is absent, not because it has been consciously or unconsciously suppressed, nor because it has been replaced by some other emotion, but

simply owing to the fact that the emotional capacity of the individual is much below normal or even absent. A lunatic, for instance, may perform acts of prodigious valour, but they are merely the acts of lunacy, devoid of affective tone. Similarly it is well known that the unimaginative individual is often the most brave, because he is incapable of appreciating the probable consequences of his actions. Closely allied to this is "Dutch courage," where the higher nervous centres are dulled by the action of alcohol, and perception and judgment are grossly interfered with.

THE OBJECTIVE METHOD OF INQUIRY.

Such is my attempt to sketch the lines along which courage has been studied by the lay writer. We must now turn aside and follow another path—namely, the psychological one—and see in what direction it leads us. At the outset of any psychological inquiries the layman may quite properly and justifiably adopt a critical attitude and demand to know what *method* it is proposed to use. He will have no difficulty in understanding that A can investigate the *bodily* organs of B and study their behaviour both in health and disease, but an inquiry into the *mental* activities of B is quite another matter, seeing that its success largely depends on B's acquiescence in the inquiry. Or B may be willing to acquiesce in A's investigations, but A's methods of approach and his interpretations of B's mental activities may be unconsciously prejudiced by certain views entertained by A which are very dear to him. Thus crudely expressed we have the essence of the difficulty which surrounds all psychological inquiry. For thousands of years man has been interested in the study of his own mind, and has adopted for that purpose the obvious or common-sense method of introspection. The fact that this academic or intellectualistic psychology has been largely barren of results is attributable to fallacies inherent to the method, for it does not tell us what man is, but what he thinks and feels and likes himself to be.⁹ This method was therefore discarded in favour of a more *objective* method of inquiry, which concerned itself particularly with behaviour—that is to say, with what the organism was doing. More recently the behaviourist school has been reinforced and finally replaced by another which, no longer content to ask "What is the organism doing?" insists on prosecuting the almost impertinent question "Why is the organism doing it? Why doing this and not doing that?"¹⁰ The founder of this school is Freud, whose persistence in the pursuit of truth has evoked the admiration even of those who most differ from him. Now since Freud is a name which probably has for most of this assembly a significance which differs from that which it has for me, a few words of explanation are indicated. Freud's investigations, originally confined to abnormal mental conditions, led him to the view that the root of the abnormality lay in a struggle between two forces—namely, the instinctive impulses and the repressive forces. The idea of mental conflict is the basis of all Freudian psychology. As the result of this conflict experience based on instinctive impulses, or rather on impulses associated with the primitive instincts, unless converted into other channels, frequently comes to be buried or repressed owing to its incompatibility with social standards, and Freud postulated a new region of the mind, termed "the unconscious," which serves as a sort of reservoir for all experience thus repressed. By the term "the unconscious" we denote all experience which cannot be brought into the field of consciousness by any of the *ordinary* methods of memory or association.⁸ Further, the content of the unconscious is essentially affective or emotional in character, and although buried, it continues to exert an influence on the conscious. The content of the unconscious can, however, be brought into the field of consciousness under certain conditions—namely, in dreams, in hypnotic states, and by Freud's particular method of free-association or psycho-analysis. It is well known that Freud, as a result of his investigations, was led to the conclusion that the great bulk of repressed experience

was connected with the sexual instinct. This conclusion has failed to find anything like universal acceptance, but Freud's claim to fame does not rest on his interpretations, but rather on the new conceptions which he has advanced concerning the *mechanisms* of mental activities, as I have briefly sketched them. These conceptions will in all likelihood share one day the fate of many other theories, but for the present they provide a consistent working hypothesis which has already stimulated psychological inquiry to a quite remarkable degree. For these reasons it is preferable to make use of them, rather than reject them because in certain hands they "have sometimes led to the discovery of unpleasant aspects of human nature or because they come from Vienna."⁸

THE COMPARATIVE OR BIOLOGICAL METHOD.

The Freudian psychology is, however, open to one important criticism, especially when it is applied, as its adherents are now applying it, to normal behaviour, and the criticism is that its point of view is essentially human and ignores biological considerations. It recognises the evolution of the adult from the child, but is silent concerning the evolution of the species. The comparative or biological method is naturally free from this objection, and is the one along which I particularly wish to direct your thoughts to-day. While free to make use of the mechanisms of mental processes as enunciated by Freud, its outlook is far wider and embraces the whole range of animal life. In its study of man the comparative method adopts the point of view that man as a solitary animal is unknown, that he is not completely free to act as his individual fancy dictates, but is subject to certain instinctive influences, some of them common to all animals and to others that are not.

As you are doubtless aware, it is not always easy satisfactorily to differentiate between instinct and intelligence. Instinct is innate and independent of experience, whereas intelligence is acquired in the light of experience. But in any intelligent behaviour it is often difficult to exclude innate factors, while conversely it is difficult, especially in those animals, such as man, which are born in a state of great immaturity, to exclude individual experience however instinctive their behaviour may appear to be. The instincts common to all animals, or primitive instincts, are two in number.³ First is the instinct of self-preservation, which can be subdivided into (a) the purely appetitive instincts underlying nutrition with their corresponding affective states of hunger and thirst, attraction towards the useful and repulsion towards the harmful, and (b) the danger instincts, with their various modes of reaction such as flight and aggression. The second is the reproductive instinct, again divisible into (a) the purely appetitive, and (b) the parental instinct; with this we are not concerned to-day.

Now it is important to observe that all instinctive reactions are accompanied by *feeling*, in such a way that the emotions may be regarded as the affective aspect of instinctive reactions. For example, the primary states of pleasure and pain are the psychical accompaniments of the fundamental reactions of attraction towards the useful and repulsion towards the harmful. Similarly the reproductive instinct is associated with the emotion of love and passion, and in its parental aspect with the tender emotion, especially that of the mother towards her young. Again, in respect of the instinct of self-preservation we find the emotion of fear associated with reaction to danger by flight and the emotion of anger with reaction to danger by aggression. These emotions, moreover, are exceptionally powerful, as evidenced by the conduct of the animal when completely under their influence and by the gross physical alterations which they effect. The common phrases "half dead with fear" and "beside oneself with anger" bear ready witness to these facts. From the biological point of view we are justified in regarding these emotional states as being purposive, in so far as they tend to reinforce the instinctive reaction. Thus not only does the tiger,

when cornered, fight with greater vigour because he is angry, but, in addition, the physical changes associated with anger, by increasing the blood-supply to the brain and muscles, render him more efficient. Correspondingly in those animals whose normal reaction to danger is by flight, fear reinforces the instinct and renders their flight prompt and successful. The same is, of course, true of the sexual instinct, as evidenced by the ferocity and restless activity of the male in the breeding season, and by the vigour, I had almost said courage, displayed by the mother in defence of her young.

THE GREGARIOUS INSTINCT.

In addition to the two primitive instincts we can recognise a third instinct—namely, the social instinct, through the agency of which cohesion is maintained in the herd, or group, or society. This is often called the gregarious instinct, under the influence of which the individual members of the group unite in common action for furthering the welfare of the group.† Three types of gregariousness can be identified, the aggressive as exemplified by the wolf pack, the defensive as exemplified by the sheep, and the socialised as exemplified by such varied species as the worker bee, the penguin, and man. Gregariousness, then, is not a modern or superficial condition, but a very old and fundamental one, and has certain distinguishing features. The first of these is the preference shown for companionship and the feeling of comfort and security derived therefrom. The second feature is the homogeneity of the herd or group; this is attributable to the suggestibility of its component members and to their specific sensitiveness to suggestions which come from the herd. The obvious effect of these conditions is to ensure that each individual shall conform to the behaviour of his fellows and shall show preference for herd opinions as opposed to any others. They are evidently not the conditions to encourage originality. The sensitiveness of the herd is well seen in the sheep in the rapid but silent manner in which the approach of danger is communicated to the flock. Now the sheep is a timid animal that reacts to danger by flight, and its timidity, together with the sensitiveness of its individual members which allows of the rapid communication within the herd of the approach of danger, represents a mechanism for defence. Similar suggestibility and sensitiveness are manifested in aggressive societies such as that of the wolf and dog by the howling of the pack and "the cry of the hounds." Thirdly, the gregarious animal is susceptible to leadership, provided that the leadership is for the good of the herd as judged by herd opinion. In other words, there is a submissiveness of the individual within the herd and a resistiveness of the herd itself to individuality. Fourthly, in all gregarious animals we have to recognise the existence of what has been called herd impulse, by which is denoted a force which is capable of endowing outside influences with the energy of instinct and of conferring instinctive sanction both to beliefs and action. This surely is the idea underlying Montaigne's aphorism: "Custom is a second nature and no less powerful." The primitive instincts, then, of self-preservation and reproduction control from within and the herd instinct from without, and in the latter we can already identify the germs of what we call public opinion. It will further be evident that the gregarious instinct must at times be opposed to the more primitive instincts and so introduces a factor which promotes mental conflict. In many respects, however, it reinforces the primitive instincts and facilitates the performance of their reactions.

Man differs from the infra-human animals not in being devoid of instinctive feeling, but in having a larger intelligence which permits him to respond in so great a variety of ways that the instinctive character of his actions is often not obvious in his behaviour. He has further acquired the capacity to divert the energy arising from instinctive impulses

into other channels, artistic, æsthetic, athletic, and so on, and has developed within the herd an individuality which tends to increase with every advance of his civilisation. In spite, however, of his greater individuality and increasing freedom within the herd, it remains a mistake to regard man as fundamentally independent of his biological history, however pleasant this view may be to the intellectualist; and seeing that man's personality is incomplete apart from the herd, it follows that human psychology must always be the psychology of associated man, for man as a solitary animal is unknown.

THE INFLUENCE OF HERD INSTINCT ON HUMAN BEHAVIOUR.

The evidence that man is gregarious is overwhelming, and the influence exerted by herd instinct on human behaviour is manifested in many directions. His intolerance of solitude, for example, both physical and mental, is seen in his desire for companionship and is reflected in the proverb "Out of sight, out of mind." It is further responsible for his hesitation in advancing new opinions, for the chilly reception which he accords them, and for his reserved and somewhat belated recognition of the courage displayed by those who insist on maintaining them. His relations with his fellows are dependent upon their recognition of him as a member of the herd, and the formalities subserving mutual recognition are correspondingly important while the strictest observance is enjoined in their performance. These formalities, moreover, whether it is the hand-shake, the raising of the hat, or the salute, are comparable to those employed by other gregarious animals such as the dog, however much the intellectualist may strive to confuse their identity. It would even appear that speech was primarily introduced to subserve mutual recognition rather than exchange of ideas, and it is noteworthy that ordinary conversation is largely confined to subjects of common interest to the herd, such as the weather, or the morning news which everybody has read. Another prominent feature of man's gregariousness is his suggestibility and his greater sensitiveness to the voice of the herd than to any other influence. Feeling is dominated by herd opinion, and reason cannot enforce belief against herd suggestion; experience before it is accepted must meet with herd approval, and this again leads to delay and hesitation in acceptance. Consequently we find that settled opinions, many of them irrational, are characteristic of the societies, classes, and cliques of which the modern herd is composed, but the force with which such opinions are endowed by herd impulse more than compensates for their irrationalism and for the slender knowledge on which they are based. We derive much comfort from certitude, and are easily deceived by custom. The truth of these statements is obvious when we realise the enormous import of the expression "bad form," and our irresistible tendency to "lay down the law" and express confident opinions on subjects concerning which our ignorance may be complete. There is a wealth of meaning in the Gilbertian lyric—

"Every boy and every girl that's born into the world alive
Is either a little Liberal or else a little Conservative."¹¹

It is owing to somewhat similar considerations that the most satisfied members of the herd are often the most dull, for they attain mental certitude and comfort by implicit obedience to the voice of the herd and by an indifference to experience amounting almost to hostility. In this class are to be found the more reactionary elements, who nevertheless take pains to invite compassion by the use of some such idealistic title as "Die Hards." Compare, too, the readiness with which the herd entrusts authority to the orthodox and the old, to those in fact who, timid of novelty and shunning the enthusiasms of youth, "do nothing in particular, and do it very well."¹¹ "Men of age object too much, consult too long, adventure too little, repent too soon, and seldom drive business home to the full period, but content themselves with a mediocrity of success."¹²

† In the following pages the views elaborated by Trotter have been closely and often literally followed. (Vide ref. 9.)

THE UNCONVENTIONAL TYPE.

But besides the "stable," or resistive class, with its orderly, stereotyped habit of mind, there is to be found in modern society, and in ever-increasing numbers, a diametrically opposite one, whose energy, enthusiasm, unorthodoxy, and instability are derived largely from their incapacity to assimilate unwelcome experience by the simple process of false rationalisation and indifference. Moreover, it is on the presence in the herd of the unconventional that progress largely depends, and an illuminating feature of the war and post-war period has been the increasing tolerance manifested by the community to the activities of what in the broadest possible sense may be called the unstable. In the past these individuals, pioneers and extremists, have paid the heaviest penalties for their preference for originality and ideals rather than for herd opinion, and have faced with dauntless heroism the dungeon, the rack, the scaffold, and the stake. With their larger perspective so often opposed to the more limited outlook of the herd, they lack the mental comfort which characterises the "stable," and their capacity for brilliance of conception and boldness of execution is seriously handicapped by their erratic disposition and greater proneness to fatigue. Any discussion on courage must be incomplete unless attention is drawn to these facts, for during the war we were witnesses of the spectacle of individuals of the most varied temperaments and upbringing being brought into an atmosphere wholly foreign to their natures, and displaying evidences of courage and endurance at a cost to themselves which it was often difficult to understand and almost impossible to estimate.

Further evidence of the gregariousness of man is to be found in his increased susceptibility to leadership in war—i.e., when the whole herd is threatened; the tremendous influence exerted by Lord Kitchener provides a recent example of this. It would also appear that the wide and traditional acceptance of the analogy so often drawn between Christ and His Church and a shepherd and his flock bears testimony to the same characteristic of human society.

PUBLIC OPINION.

These various evidences of gregariousness in man may appear to have little to do with the subject of this lecture. Attention is directed to them, however, in order to emphasise the enormous importance of herd instinct in the influence which it has exerted throughout the whole history of man, and is exerting at the present time. I now pass on to consider another element of gregariousness to which brief allusion has already been made under the name of public opinion. We have learnt enough of herd instinct to realise without further elaboration that the origin of our moral codes is to be found in herd opinion. In the rites and solemn ceremonies of primitive man we can detect the germs of modern conventions, sanctions, and laws, and the energy imported to these by herd impulse explains the almost unlimited power which lies behind them. Moreover, seeing that in gregarious animals below man the welfare of the individual is subordinated to that of the herd, it is impossible to avoid the conclusion that altruism is a product of the gregarious habit, and must therefore be regarded as being just as natural as any other instinct.¹³ It has been computed, for example, that the average worker bee, deaf to all voices other than that of the hive, works herself to death in about two months; she does it, moreover, with exuberant energy and every appearance of joyfulness, a little fire ablaze with altruistic feeling and unselfish enthusiasm.⁹ Again, the dog, accustomed originally to obey the voice of the pack and now subservient to a human master, will spontaneously return to his master to receive the punishment he knows he has merited with every appearance of guilt. Herd instinct, in fact, introduces a mechanism by which the sanctions of instinct are conferred upon acts by no means acceptable to the body or mind, a mechanism in which originates the sense of duty, conflicting often with the more primitive instincts of

self-preservation and reproduction. According to this argument, it is a mistake to regard man as an intrusion into the world, fundamentally independent, splendidly isolated, divorced from history, responsible to himself alone; on the contrary, it is far more rational to regard not only the bad but also the good elements of man's behaviour as products in no small measure of his development. However complex his behaviour, however obscure his motives, man is sensitive to the call of duty, of love, and of honour, altruistic, generous, and courageous not because reason recommends it, but because he must be.⁹

MECHANISMS TO ENSURE SAFETY.

Let us pause for a moment and take stock of the views we have attempted to formulate. It has been pointed out that the psychology of man is largely determined by his biological history, and that his conduct, being largely instinctive, is open to generalisation to a far greater extent than is sometimes supposed. In addition to the primitive instincts, man, like many other animals, is subject to herd instinct, modifying, and often conflicting with, the former, while both frequently conflict with experience. It has further been emphasised that the instincts are associated with various emotional states which serve to enhance interest and facilitate the successful accomplishment of instinctive reactions. We have seen, also, that altruism is an essential product of the gregarious instinct and that in the energy derived from herd opinion we can identify the germs of the moral codes by which human society is governed and controlled. Seeing, therefore, that the welfare of the herd predominates, it is not surprising that mechanisms have been evolved to ensure its safety. One such mechanism, I submit, is courage, which though called by that name only where man is concerned is not wholly unrepresented in animals. Owing to his greater intelligence and broader outlook, man can not only respond to any threatening situation in a variety of ways, but also has a far greater variety of threatening situations to respond to. Consequently the scope for the display of courageous qualities is enormously increased in man, so that we recognise beside physical courage, the courage we call moral, manifested in the field of art, of politics, of religion, and commerce. Moreover, owing to the greater individuality of man, entailing wide differences in adaptation, it happens that our mode of response to the same set of circumstances is subject to wide individual variations. So, too, there is a curious specificity about courage, as seen from the fact that a woman may present a bold front to a burglar and flee in terror from a mouse. "There is a courage of the Cabinet as well as a courage of the field; a courage which enables one man to speak masterly to a hostile company, whilst another who can easily face a cannon's mouth dare not open his own."¹¹

"PURE" COURAGE.

If now we review the forms of courage previously alluded to in the light of what has been learnt, it is easy to understand that "pure" courage represents the perfection of the psychological processes which have as their object the successful response to danger. Here fear, the presence of which in anything like an acute form would inevitably interfere with the response, is completely suppressed by a process which is wholly unconscious, and the individual, or unit, is free to deal with the situation calmly and unperturbed. It has recently been suggested⁸ that man's normal mode of reaction to danger is by manipulative activity, and that if his freedom of action is interfered with fear tends to obtrude into consciousness. This view finds support in the universal experience that trench warfare against an unseen enemy is infinitely more trying than a war of movement. Another form of courage is that in which the emotion of fear is replaced by some other affective state, of which anger is the most common, but by no means the only one. This form of courage admirably illustrates the complexity of man's behaviour, for the emotional forces which underlie it may be of the most varied kinds, such as

love of notoriety, covetousness, personal pride, religious enthusiasm, and so on. This aspect of courage in a recent article in the *Times* has been quite inappropriately termed the "courage of ignorance." In contrast with these two forms of courage which we may call the courage of fearlessness, there is the courage despite the presence of fear, or the courage of fearfulness. Here the enormous power wielded by herd opinion, in the shape of an *instinctive* sense of duty, comes into play, and ensures that the unit, be it XI. or XV., regiment or squadron, class, or nation, shall not be jeopardised by the frailty of its individual components. Was there not once a Spartan boy, who to escape the disgrace of being branded a thief permitted the fox which he had stolen and concealed under his tunic to gnaw into his entrails? "I can well die but I cannot afford to misbehave."¹¹

COURAGE AND MENTAL HEALTH.

Human courage, then, in all its forms, may be regarded as a defence-mechanism of great complexity and great efficiency, and the universal esteem in which it is held, by conferring upon it the force and energy of herd instinct, adds enormously to its usefulness to the community. The efficiency of this mechanism is subject to the rules which modify mental health in general, for courage may be properly regarded as evidence of the existence of mental health. Now health of mind depends on the presence of a state of equilibrium between instinctive tendencies and the forces by which they are controlled. Weakening of the latter from whatever cause leads to the development of various abnormal states, the character of which largely depends on the particular "make-up" of the individual affected. The most frequent cause of weakening of the controlling forces is undoubtedly fatigue, the result of long-continued stress and strain, loss of sleep, exposure, and so on. In the air an additional factor is operative—namely, the defective oxygenation of the blood, and consequently of the brain, which occurs at high altitudes. During the war the conclusion was repeatedly forced upon me that courage and morale tend to evaporate at high altitudes, and I believe it was owing to this that relatively few decisive combats were fought at the greater heights to which your machines could attain. Under conditions of stress the normal controlling mechanisms become weakened, and fear which had hitherto been completely suppressed, gradually obtrudes into consciousness. This at once introduces an element of conflict, since fear, owing to its incompatibility with social standards is regarded with shame, and its further intrusion has to be resisted at all costs. Thus begins the process of *conscious* repression which in many cases is successful in restoring the normal mechanisms. In others, however, and especially when the conditions of stress persist, conscious repression fails in its object, and a state of anxiety, with its attendant physical and mental manifestations, gradually supervenes.⁸ The development of such anxiety states is essentially due to fatigue of the higher controlling mechanisms. Now fatigability is a characteristic of all living things and its natural remedy is rest, and it is important to recognise that alternating periods of activity and rest are merely illustrations of the rhythmicity which pervades all life, as evidenced by the seasons of the year, the ebb and flow of the sea, the beat of the heart, and the states of asleep and awake. "To everything there is a season and a time to every purpose under the heaven; a time to be born and a time to die, a time to break down and a time to build up."¹⁴

THE OBJECT OF MILITARY TRAINING.

The more military applications of these various considerations are obvious from the fact that the essential object of military training is to establish morale and enhance the homogeneity of the herd. This is effected in various ways. Your leaders, generally speaking, have been recruited from a class in which respect for tradition and custom figure prominently; accustomed to rule as lords of the land, they

have been wont to indulge their leisure in vigorous and dangerous sports and pursuits, and to cultivate the spirit of adventure under a strict, if somewhat inelastic, code of class discipline. Drill, again, encourages responsiveness and increases the awareness of each individual of what is passing in the minds of his companions. In addition to the processes of habituation and heightened suggestibility which characterise regimental life and lead to cohesion, morale is further strengthened by the wise and systematic use of sublimation. By this term is denoted the process in which the energy arising out of conflict is diverted from some channel which leads in an asocial or antisocial direction, and turned into one leading to an end connected with the higher ideals of society.⁸ This is the significance of *esprit de corps*, pride of regiment, belief in a cause, and, in fact, of all those influences by which a soldier is encouraged to set so high a value on his duty towards his comrades that he is ready to die in its execution.

"We would not die in that man's company
That fears his fellowship to die with us."¹⁵

The innumerable manifestations of courage and endurance exhibited during the war were only rendered possible by this spirit of comradeship, and in this and in the use of mass attacks we recognise unmistakable evidences of gregariousness. A further instance of the heightened suggestibility of the well-trained soldier is to be found in the contagiousness of courage; it is "caught as men take diseases one of another"¹⁶; and may rapidly infect a whole army. There are, I think, indications at the present time that those responsible for military training in this country, without in any way losing sight of the inestimable importance of all those factors which make for disciplined cohesion, are more inclined than they have been in the past to pay attention to the psychology of the individual soldier. This question is of particular significance in a force such as yours, where, from the very nature of your duties, individualism must always be more prominent than in other branches of the Service. It is at any rate certain that responsiveness and automatic obedience to orders can be overdone. "The success of the Captain of Koepenick, for example, could only be possible in an army whose members had, through a special course of training, reached such a pitch of responsiveness to the commands of men in uniform that they obeyed without question the ludicrous orders of a cobbler."⁸

CONCLUSION.

In this study of the psychology of courage I have attempted to expose the fallacies inseparable from the purely intellectualistic method, and the limitations imposed by a view which regards courage as the sole prerogative of man. Especially is the wide divergence of opinion as to the type of individual, or class, likely to exhibit courage to be explained by the fact that courage has been too often regarded as an isolated quality of isolated man, while the motives underlying it have been consistently ignored, presumably because they are sometimes unsatisfactory. I would ask you once more not to be misled into thinking that courage loses anything of beauty or nobility because evidences of its existence are to be found in animals lower, much lower, than ourselves. It cannot surely handicap a young soldier to know that the seeds of courage have been sown in him by Nature? We have to be courageous or fail in our struggle for supremacy. For nearly three years of war I was permitted by a fortunate chance and the kind indulgence of my superior officers to be a safe, yet intimate, witness of many of those acts of irreproachable courage which stand to the credit of your Service; so close an insight into the mysteries of courage only served to enhance my admiration and arouse my curiosity. But curiosity as to its nature will never prevent us from idealising courage. Courage, from whatever angle we approach it, whatever origin or purpose we assign to it, no matter what form it assumes, nor even what motives underlie it, will always be a quality beloved of man. The courage of attack, the

courage of defence, the courage of art, the courage of debate, the courage of motherhood, the courage of grief, the courage of adventure, the courage of ill-health, the courage of the martyr, the gambler, and the spy, each for itself we respect and admire. And, after all, "it is not life that matters, but the courage that we bring to it."

Three Lectures

ON THE

CULTIVATION OF TISSUES AND TUMOURS IN VITRO.

Delivered at University College, London.

By A. H. DREW, D.Sc.,

IMPERIAL CANCER RESEARCH FUND.

LECTURE I.*

(Delivered on Feb. 28th, 1923.)

THE TECHNIQUE OF TISSUE CULTURE.

In this course of lectures I propose to deal with the cultivation of tissues in media under three separate headings. In this, the first lecture, we shall have to consider the subject from what is perhaps its least interesting aspect—viz., the technique which it is necessary to adopt in order to obtain cultures, and having obtained them to keep them growing continuously in subculture. In the second lecture I propose to deal with the question of the growth of normal tissues in vitro, and in the third and last lecture to discuss the application of the method to cancer research and to consider some of the results obtained from a study of cultures of tumours in different media.

THE PLASMA MEDIUM.

Although in the past many different media have been tried with greater or less success, the only two which have proved to be really successful are a plasma medium and a saline medium recently devised. It will be necessary, therefore, to consider the best methods for obtaining plasma, and the preparation of the saline medium. Although in America chicken plasma has been more used than any other and chicken tissues chiefly studied, I propose to discuss the growth of mammalian plasma. One of the most convenient animals for such a purpose is the rat, which gives a good yield of plasma, in which grow readily not only rat tissues, but those of the mouse, guinea-pig, and rabbit, and doubtless many others.

Rat Plasma.

In order to prepare plasma from such an animal as the rat a number of instruments are required in the following order. Three or four pairs of sterile forceps, two pairs of stout scissors, and a pair of bone-cutting forceps. A long glass tube, about 5 mm. in bore, into one end of which is fused a stout, hollow platinum needle. This tube is coated with

a mixture of hard and soft paraffin, by being immersed in a deep vessel containing equal parts of paraffin melting at 45° and 58° C. The tube is withdrawn from the molten mixture and quickly drained, care being taken to see that the needle is not choked. The tube is stored till required in a copper vessel, which is cooled by a mixture of ice and salt. Three or four ordinary Pasteur pipettes are coated with paraffin and cooled in the same manner as the needle. Two or three centrifuge tubes are also paraffin-coated and cooled, and a few small test-tubes treated in the same manner. (Fig. 1.)

FIG. 1.

1. Platinum needle fused into glass tube and coated with paraffin, for obtaining blood from heart.
2. Paraffined Pasteur pipette for plasma.
3. Right-angled pipette for saline medium.
4. Paraffined tube for storing plasma.
5. Paraffined centrifuge tube for plasma.
6. Glass capsules for storage of tissues.

The rat is anaesthetised with ether, pinned out, and the thorax opened aseptically. The heart is exposed and steadied with forceps, and the platinum needle plunged into one of the ventricles. The blood is allowed to flow into the tube till the flow slackens, when the tube is withdrawn and the contents are at once run into the centrifuge tubes, which are ice-cold. These are placed in the buckets of a centrifuge and the blood at once centrifuged at high speed for three minutes. The clear supernatant fluid is pipetted off with a cold paraffined Pasteur pipette into a second centrifuge tube, and the plasma again rapidly centrifuged for one minute. With a paraffined pipette some three-quarters of the supernatant fluid is pipetted off into a small paraffined test-tube, which is at once placed in a copper vessel surrounded with ice and salt, where it remains till required. Such a plasma, although it will give limited growth of embryonic tissues for a few generations, is not suitable for continued cultivation, for which the addition of an embryonic extract is necessary.

Embryo Extract.

Young embryos of the rat or mouse are taken at about the twelfth day. The parent is anaesthetised and the abdomen opened with aseptic precautions. The embryos are removed and are placed in a sterile Petri dish and covered with Locke's solution. They are next removed from the membranes and washed in another dish with Locke. They are next cut up with sterile scissors into coarse fragments, and the fragments transferred to several changes of Locke to free them from blood. This is essential, as more than minimal traces of blood inhibit growth. As soon as all obvious traces of blood have been removed, the embryo fragments are placed in a small tumour mincer (Fig. 2) and are finely minced. The pulp is transferred to a sterile tube and an equal volume of Locke's solution added, and the mixture is well shaken. It is then frozen and thawed twice to disintegrate the cells, and centrifuged at high speed for 15 minutes. The clear fluid is pipetted off and constitutes embryo extract. As an additional

* Lectures II. and III. will appear in coming issues of THE LANCET.

precaution the extract may be filtered through a Berkefeld filter.

THE SALINE MEDIUM.

With the saline medium no plasma is required, but the addition of embryo extract is necessary. The saline medium has the following composition:—

Saline Constituents of Medium.

NaCl	..	..	..	0.900	CaH ₂ (PO ₄) ₂	..	..	0.010
KCl	..	..	..	0.042	MgHPO ₄	..	..	0.010
NaHCO ₃	..	..	..	0.020	H ₂ O	..	..	100.0
CaCl ₂	..	..	..	0.020				

In actual practice it has been found convenient to make up the six saline solutions separately, and of ten times the final strength. The magnesium salt is not soluble, but if it be suspended and steamed with the other salts, solution takes place. These solutions can be kept in stoppered bottles, and when required aliquot quantities can be pipetted off into a flask, and sufficient distilled water added to give the requisite concentration. A complication is introduced by the necessity of steaming each of the two calcium solutions, and the sodium bicarbonate solution separately from the other saline members of the final solution; unless this be done no growth will take place. To make up 50 c.cm. of culture solution 5 c.cm. of each of the solutions of sodium chloride,

FIG. 2.

1. Mincer for mixing embryos for the preparation of embryonic extract. 2. Knives for cutting up tissues.

potassium chloride, and magnesium hydrogen phosphate is added to 20 c.cm. of distilled water in a small flask. This mixture, the two calcium solutions, and the sodium bicarbonate solution are then steamed separately for ten minutes. When all these have cooled, 5 c.cm. of each of the calcium solutions and 5 c.cm. of the sodium bicarbonate solution are added and the salt mixture is ready for use. In order to use either the plasma medium or the saline fluid, embryo extract is necessary, and for general use we find the best strength to be about one part of the embryo extract to four of plasma or of saline.

PREPARATION OF TISSUES FOR CULTURE.

A pregnant rat or mouse is selected and the abdomen opened with strict aseptic precautions. The embryos are removed and placed in a sterile, covered dish and covered with Locke's solution. With fresh sterile instruments the embryos are removed from the membranes, and whatever organ is desired to cultivate is removed and transferred to a capsule containing some of the saline culture medium. The organ is cut into coarse pieces and washed in several changes of saline, so as to free it as completely as possible from all traces of blood, which exerts a definitely inhibitory effect on growth. The washed pieces should then be transferred to a sterile capsule, kept moist by a few drops of the salt medium, and cut up with fine knives into small pieces about 1 mm. square.

Culturing.

Sterility is, of course, of the utmost importance in culturing tissues, and although all the operations yet described can be carried out with care in any ordinary laboratory, those now to be described must be performed under cover. For this purpose a metal and

FIG. 3.

Box for putting up cultures with metal table for cover-glasses and rack for slides.

glass case, shown in Fig. 3, will be found very convenient. This case contains a glass rack for the hollow slides used and a metal table for the cover-glass. The whole apparatus is flamed out with a Bunsen and the metal table thoroughly heated. The slides, which are stored in absolute alcohol, are seized with forceps, rapidly flamed, and arranged on the glass rack. Cover-glasses are cleaned with chromic acid mixture and are washed and stored in ether. They are removed one by one with forceps, flamed, and laid on the metal table. In order to culture tissues in the plasma embryo extract medium portions of the tissue are transferred with iridectomy knives to the centre of cover-glasses. With a sterile

FIG. 4.

Amitotic division in cell induced by hypotonic fluid (commencement).

pipette a measured volume of the embryo extract is added to each and then three volumes of the plasma. The mixture is stirred rapidly with the knife, the fragments arranged, and allowed to clot. As soon as clotting has taken place the cover-glass is inverted over a well-slide and sealed up with paraffin. Cultures into the saline embryo extract medium are made in a like manner, except that the saline solution and the embryo extract are mixed first in a separate tube. A drop of the culture fluid is placed on the cover-glass,

Thus very briefly are seen some of the changes as they affect the sacro-iliac joint, though mention should be made of an intermediate stage which D. E. Derry¹¹ has shown to exist, in cases when, in spite of the assumption of the erect attitude, the

transverse process elements occasionally persist. He has described several specimens of ilia with post-auricular facets, one or two in number, in the form of prominences on the ilia, either passing to meet ligamentous attachments on the sacrum, or being actual facets articulating with the first, second, and third sacral vertebral transverse elements. This condition shows a transitional state of affairs between that in the pronograde and orthograde animals, the post-auricular facets being relics of the transverse process contact of the former.

In the maintenance of the erect attitude, the posterior portion of the iliac bones is drawn backwards and downwards by the pull of the gluteus maximus and hamstrings through the sacro-sciatic ligaments; so that a sharp sciatic notch is produced, though here again a sexual difference may be observed, for the female sciatic notch is not so sharply angled as the male. In this way it may be said that the female pelvis contains more of the horizontal pelvic characteristics than the male, in that—

- (a) The sciatic notches are less sharply angled.
- (b) The ilia are longer, less curved, and less backwardly bent.
- (c) The sacral articular surfaces of the sacro-iliac joints represent only 2 to 2½ sacral vertebrae.
- (d) The body-weight being transmitted more through the front part of the first sacral vertebra, the anterior or cranial end of the sacrum tilts more forwards, the posterior or caudal more backwards, producing a movement known as nutation of the sacrum, which is a rotation through the second sacral vertebra.
- (e) The presence of the pre-auricular groove, commoner in women. Derry¹¹ says: "In diarthrodial joints the amount of grooving or constriction of the bones forming that joint for the attachment of ligaments is in direct proportion to the amount of movement thereat—e.g., the head of the femur moving on the fixed acetabulum is the more grooved for capsular attachment, or the condyle of the jaw in the immovable glenoid fossa, similarly."

So with the sacro-iliac joint, the female ilium moves on the more immovable sacrum, and shows a grooving of the bone anteriorly, the so-called pre-auricular groove. Whereas on the male bones, where there is normally next to no movement of ilium on sacrum, owing to the amount of bony interlocking that takes place of both articular surfaces, no such groove is found.

Gross Anatomy.

The sacro-iliac joint is now classed as a diarthrosis, the bony elements being the articular surfaces of the two bones, which are covered with cartilage that looks like hyaline, but proves histologically to be fibro-cartilage, that on the sacrum being the thicker and more fixed. It was not till Goldthwaite and Osgood¹ wrote their paper on these joints that much attention was focussed on them, and even now several textbooks of anatomy have not gone out of their way to correct their old and erroneous statements.

The capsule of the joint is formed by the intrinsic ligaments which are too well known to need mention and is weakest inferiorly. That this is so is shown by the following points:—

1. Disease of the joint most often points this way.
2. In puerperal sepsis a path may be opened into the joint here.
3. Rupture of the joint takes place here, as, for example, after symphysiotomy and other such strains on the pelvic girdle; though a compensatory hypertrophy of the anterior ligaments sometimes takes place, for in cases of absence of the pubic symphysis full activity even to uncomplicated pregnancy has been recorded.
4. Frequent implication of the lumbo-sacral cord in pathological conditions of the joint, the cord being a constant relation of the lower third anteriorly, so that the irritation of it explains the sciatic and other pains so common in lesions of this joint.
5. Naked-eye inspection, when on moving the bones together the capsule is seen here to be thin and stretched; further pouches of synovial membrane bulge out quite readily along the anterior aspect of the joint.
6. From the weak markings of the bones anteriorly.

The synovial cavity, seen best by injection with coloured gelatin either beforehand or during dissection, is considerable in extent, extending posteriorly in small pockets behind the auricular surface the whole of the way down, or being encroached on posteriorly

by the ligamentous fibres that go to form the interosseous ligament. Further, the laxity of it is shown by pressing the bony surfaces together when the membrane is seen to bulge in small pockets along the anterior aspect of the joint. Sections through the joint in a series of pelves, taken in a vertical and oblique direction, between corresponding points, show a definite sexual distinction, the male joint cavity being much more tortuous by reason of the bony interlocking, whereas the female is much less tortuous with very little interlocking, thus permitting greater freedom of movement. This was observed in a series of dissecting-room bodies—where naturally the joints showed considerable cartilage erosion, osteoarthritis, and varying degrees of ankylosis—and further confirmed on post-mortem bodies.

Movements.

1. Careful study shows that the pelvic articulations are fashioned to make movement possible in certain directions, the function of such movement being to lessen jarring and straining. Stability is dependent on the tone and character of muscles and ligaments, and anything interfering with the stability of the pelvis interferes with the use and development of the muscles and ligaments attached.

(a) With regard to the pubic bones, the muscles give no support and the ligaments afford but little strength and stability. Further, as mentioned above, the pubic bones may be absent and full activity even to uncomplicated pregnancy ensue. What movement there is at the pubis, of up and down play, is only possible in so far as there is relaxation and movement at the sacro-iliac joint.

(b) At the sacro-iliac joint movement consists of a tilting of the ilium on the sacrum. Further, because of a double obliquity of the joint surfaces, a moving back of the upper part of the sacrum, which is wedge-shaped with the base of the wedge anterior, increases the antero-posterior diameter of the pelvic brim; also by pushing the ilia laterally, so increases the transverse diameter also. Owing to the "nutation" of the sacrum, increased inlet measurements of necessity coexist with diminished outlet diameters, changes that are produced by the assumption of the so-called Walcher's attitudes.

The first position shows the patient supine with the legs from the hips hanging free over the edge of the table, so producing hyperextension of the hip-joints with extreme tautening of the ilio-femoral ligaments, and also a forward rotation of the ilium on the sacrum so that the sacral promontory lies farther away from the symphysis. This movement is greatly aided by the physiological relaxation of the sacro-iliac joints during pregnancy, so contrasting with the lack of movement in the corresponding joints in the male. In the second position the thighs are sharply flexed on the abdomen, when the inlet measurements are decreased and those of the outlet increased.

It is well known that at the close of pregnancy great hypertrophy of the symphyseal ligaments takes place in the guinea-pig's pelvis, to allow the pubic bones to separate to the relatively wide interval of one inch; further, at the same time a relaxation of the capsule of the sacro-iliac joint occurs, a state of affairs that incapacitates the guinea-pig so much that during the last three weeks before labour she crawls on her abdomen dragging her femora behind her. This happens because the separation of the pubic bones allows the abdominal contents to fall forwards, and owing to the consequent flattening of the ilium, sacrum, and coccyx, as Sir John Bland-Sutton has pointed out, the leverage power of the femora is weakened. After parturition the symphyseal ligaments quickly return to their former state, though the symphysis does not regain its firmness, for in a macerated parous specimen the pubic bones fly apart. It was hoped that from a study of a series of guinea-pigs, pregnant and non-pregnant, before and after labour, some help might be obtained towards the understanding of the similar but less marked relaxation that takes place in the sacro-iliac capsules in human pelves: beyond verifying the condition found by dissection, histological evidence of the gradual hypertrophy and sudden return to normal of the symphyseal ligaments is most disappointing.

2. In this way it is seen that the chief influences that bear on the sacro-iliac joints and their movements are as follows:—

(a) Sex.—The articular interlocking precludes in the male any but a slight movement, whereas in the female the absence of interlocking and the physiological relaxation during menstruation and pregnancy, help to provide a distinct though limited range of movement.

(b) *Certain Unusual Anatomical Extrinsic Influences.*—(1) The post-auricular facets mentioned above; (2) an abnormal lumbo-sacral articulation, in which the fifth lumbar transverse process may articulate either unilaterally or bilaterally, with the ala of the sacrum postero-superiorly, or with the ilium above and behind the auricular surface, a state of affairs that will further restrict the joint movement.

(c) *Conditions Tending Towards the Pathological.*—These conditions, tending in their results toward the pathological—e.g., of occupation—were lucidly described in Sir Arbuthnot Lane's classical paper of 1887 on the skeleton of coal-heavers, bearing out his theory of the crystallisation of lines of force in the direction of stress and strain. Indeed, since the writings of Matthews Duncan and Arbuthnot Lane very little has been added to our knowledge of the mechanics of the bony skeleton.^{12 13}

(d) *Maintenance of the Erect Attitude.*—The body-weight is transmitted vertically down through the first piece of the sacrum, causing a forward nutation of that bone, a movement resisted by (1) the pull of the sacro-sciatic ligaments inferiorly; (2) the posterior sacro-iliac ligaments of great strength, which, working, with the auricular articulating surfaces as a fulcrum, tend to force out either iliac bone, but only bending them out owing to the presence of the symphysis pubis in front; and (3) the upward and inward thrust of the femora. That this is so is shown by the production of the unilaterally deformed Nägele and bilaterally deformed Robert pelvis, brought about respectively when one or both sacro-iliac joints have lesions incapacitating their movements, so that the bones give to the upward and inward thrust of the femora and cave in.

The Commoner Pathological Conditions of Relaxation and Strain.

Relaxation arranges itself under three headings:—

(1) The physiological relaxation associated with menstruation; (2) that associated with pregnancy, being an exaggeration of the normal physiological condition; (3) that due to trauma, general weakness, or some known pathological process in which various conditions predispose to joint trouble, as: (a) faulty postures, for example, standing in a position of extreme lordosis, or sitting with the lumbar curve reversed, as when lounging; (b) in stout persons with visceroprosis, the drag of the abdominal contents increases the lumbar lordosis; (c) the badly-fitting corset, again, increases the lordosis and presses on the iliac crests anteriorly. These conditions cause abnormal joint pressure and so through the stages of serous infiltration, enlargement of the synovial membrane, and separation of the bony surfaces, freer movement is produced in the direction of relaxation.

In Osgood's series only 2 per cent. showed absolute ankylosis of their pelvic joints, but he does not specify the ages of the subjects. Further, mention should be made, in the ætiological consideration of this condition, of rickets, cachexia, constitutional weakness, and functional nerve disorders, occurring most frequently in multiparous women, especially in those with occupations calling for much walking and carrying of weights.

The symptoms of this condition are very variable, ranging from slight pains in the sacro-iliac region to pains throughout the whole pelvis, unsteadiness of gait, and sometimes a complete disability.

Sacro-iliac strain may be of the following types:—

(a) *Subacute*, brought on by stooping. In this movement protection is first given by the contraction of the antagonistic muscles, next strain is instinctively relieved by hyper-extension of the lumbar spine—as will be remembered by those who have experience of long and arduous pulling in a forceps delivery, or in a tug-of-war when a wrong position has been maintained, or by pregnant women wearing too high heels, or, again, by faulty standing, or by lying supine on a hard surface. For example, post-operative backache is often caused by a patient, especially a woman, having been laid on an operating table with no support in the small of her back, so that the æsthetic relaxation of the protective spinal muscles easily brings about such a condition. Milder degrees are often seen after ordinary recumbency, when a good stretch on waking relieves any lumbar pain that may be present.

(b) *Acute*. A patient complains that something has snapped, and of difficulty in holding his body erect, with sharp pain in the lower lumbar region. This pain disappears after a rest, then reappears and becomes worse after 24 hours, when the patient is completely disabled, and the pain which has been at first localised spreads through the whole lumbar region.

(c) *Chronic*, which falls more under the heading of joint relaxation, mentioned previously. In these conditions varying degrees of damage are done to the joint, ranging from a mild trauma to actual stretching and rupture of the ligaments, occasionally with some bony displacement and subluxation.

The symptomatology of sacro-iliac strain and relaxation may be—

1. Subjective:—

Pain may be localised in the joint, or owing to the proximity of the lumbo-sacral cord it may be referred to the leg or foot. It is increased by movements that affect the joint, but not by pressure along the nerves. Generally unilateral, the pain is worse at night owing to dorsal recumbency, and is relieved by changes of position—e.g., from the dorsal to the lateral. By day in some cases it may not be present unless the joints are strained by sitting, standing, stair-climbing, or stooping. Further, in women the pain is worse at menstruation.

2. Objective, found on clinical examination:—

(a) *Abnormal Mobility.*—This is observed in cases of joint relaxation (1) by forced hyperextension of the thighs one at a time, so moving the ilium on the sacrum; (2) again, with the patient standing and the observer holding one hand on the sacrum and the other on the pubis, if the patient now raises first one knee and then the other, abnormal mobility can be noted; (3) with the thumbs on the sacrum and the fingers on the crest of the ilia, when the patient is asked to raise her legs one at a time, abnormal mobility is found: for this test the patient is best placed sitting on a chair; (4) with the patient lying on her back and raising first one leg and then the other, extra mobility is elicited by the observer laying his hands flat on the sacrum.

(b) *Certain Abnormal Attitudes and Postures.*—As for example on standing, the body is inclined to the opposite side. On rising from the sitting posture the spine is held rigid and the hands are used for support. On stooping, flexion of the spine is avoided. On walking, in acute cases, the steps taken are short to avoid spasm of the hamstrings, and in chronic cases the gait may become rolling or waddling. On sitting the patient does so on the sound side to avoid the pain from using the diseased buttock.

(c) *Limitation of Movement.*—In movement of the body on the thighs, seen in forward, backward, and lateral bending; so that in extreme cases the last-named may be so curtailed that the body is drawn forwards, and the erect attitude avoided.

In this way the objective symptoms are seen to be abnormal mobility, abnormal attitudes and postures, and abnormal limitation of movements. Albee's symptom-complex⁵ of sacro-iliac disturbance is as follows:—

1. Pain in the region of the affected joint on turning over when in the recumbent position.
2. Discomfort when lying on the back.
3. Pain when sitting on the affected buttock, relieved on changing to the opposite side.
4. Pain in the affected joint on forward bending.
5. Pain on deep pressure over the affected joint.
6. Listing of the whole spine to the side opposite the lesion.
7. Goldthwait's symptom, which is that pain is referred to the joint or to the leg of the affected side, when the thigh is flexed and the leg extended.

Finally, the danger of diagnosing over frequently sacro-iliac disturbance must be constantly kept in mind; for in a joint so difficult of access, diagnosis is very hard to confirm. As Payne⁸ has said, great care must be taken to exclude other conditions before giving the sacro-iliac joint the blame for the manifold forms of lumbar discomfort and backache.

My thanks are due to Prof. T. B. Johnston for his kindly advice.

OBSERVATIONS ON PEPTONE IMMUNISATION IN ASTHMA AND OTHER ALLERGIES.

By A. G. AULD, M.D. GLASG., M.R.C.P. LOND.,
D.P.H. OXF.

"PEPTONE" in this article represents the mixture of proteoses and peptones produced by digestion of protein. It is present practically constantly in the stomach or intestines. In the small intestine the proteoses, peptones, and polypeptides are resolved into amino-acids, which alone are admitted into the portal blood and are capable of detection by vividiffusion and other methods. No trace of peptone is discoverable in the portal blood, even after a heavy protein meal, and this is not surprising when it is considered that even such a minute quantity as 0.01 g., intravenously introduced, produces poisonous symptoms. Those amino-acids which pass the liver are quickly taken up by the tissue cells, and selected as building material for their own albumins. The cell also katalyses its albumin to amino-acids, some of which are distributed by the blood to other tissues which may require them, such as the vital organs in cases of starvation, while others are excreted as waste matter. This katabolism is effected, just as in alimentary digestion, by two ferments; one pepsin-like, acting in acid medium producing the peptones and the other, erepsin-like, attacking the peptones in an alkaline medium to produce the amino-acids.

These remarks are rendered necessary in view of the assumption, still occasionally made, that peptone passes through the intestinal wall into the blood. Thus Widal, Abrami, and Lancovescio¹ have advanced this hypothesis on the ground that the "*crise hæmoclasiq*ue" followed an Eck fistula, thus demonstrating that proteoses and peptones must have been present in the portal blood. Normally, they think these bodies are "fixed" by the liver, but if the liver is out of order, they are passed into the general circulation thus producing the "hæmoclasia"—an unfortunate expression, by the way, as it really means disruption of the red corpuscles, whereas the only constant effect of the phenomenon is a leucopenia. The fallacies underlying such a view are obvious enough. The portal blood may contain many substances, quite apart from peptone, capable of inducing the "*crise*," such as amines, which are normally transformed in the liver. According to van Leeuwen,² the so-called hæmoclastic crisis is a very ordinary affair which can be induced by all sorts of ingested substances, even carbohydrates. Zehnter³ has recently adversely criticised the phenomenon as a sign of hepatic insufficiency, his results mainly contradicting it. If proteoses were circulating in Eck fistula dogs they would give the well-known reactions, whereas the animals either show no particular symptoms or else a state of excitement.

"Digestive" Anaphylaxis.

Here brief consideration may be given to another phenomenon, that of "digestive anaphylaxis" treated either by minute oral doses of the offending substance, or by the ingestion of 0.5 g. peptone an hour before meals on the empty stomach (Pagniez⁴ and Vallery-Radot, Widal, Fatou⁵). It is affirmed that peptone so taken prevents the symptoms not only of indigestion, such as flatulence, somnolence, arrhythmia, and facial erythema (Fatou), but also urticaria, migraine, or asthma which may be excited by the digestive disturbance. This purely local action of peptone lasts for about three hours, and the dose must be repeated before the next meal. Now in view of what has previously been stated as to the abundance of peptone normally present in the stomach or alimentary canal, this method of treatment certainly looks like carrying coal to Newcastle. But the observations of Pavlov⁶ have supplied the likely explanation. He showed that the chemical excitant of the gastric juice—the

excitant of the hormone (gastrin)—was a constituent of the digestion of flesh. No other substance was capable of so acting though water had a slight effect. This constituent Pavlov found in peptone, especially a pure peptone such as Chapoteau's, as apart from proteose, so that when given before meals it creates a secretion of juice sufficient to protect the sensitive mucous membrane from the offending substance, and which in turn is more effectively digested. Extract of meat concentrated in a slowly dissolving medium is alleged by Pavlov to have an even more decided effect in producing the secretion, so that if given under similar conditions the results would doubtless be at any rate quite equal to those of peptone. Given during digestion also the hormone effect would doubtless ensue.

Immunisation by Peptone.

Immunisation by small increasing injections of peptone, avoiding apparent reaction, was based on experimental results of two kinds.⁷ In one set it was shown by Dale that when an animal was sensitised, say to three antigens, desensitisation to all three might be effected by one of the antigens. Obviously, therefore, there were no chemoreceptors and two of the desensitisations were non-specific. Dale also found that in the case of an animal immunised to a particular serum, a strip of the uterine muscle was nevertheless sensitive not only to the homologous serum, but also to a heterologous one, either of which also desensitised to itself. The other set of experiments by Biedl and Kraus, Weil, and others showed that peptone poisoning produced in non-sensitised animals the distinctive symptoms and lesions produced by the exciting dose of the antigen in the corresponding sensitised animals. As the symptoms were always identical in the same species, no matter what the antigen, the poison is evidently non-specific; hence the power of one antigen to desensitise to several. This poison also is either contained in the peptone itself or else is produced by its reaction with the fluids and tissues of the body. Hence it might be inferred that treatment with peptone would produce in the blood a protective substance against this poison from whatever source.

Although we hear of "rival" theories of anaphylaxis—the humoral and the cellular—all the available evidence points to the correctness of Bordet's⁸ view that both humoral and cellular factors can indisputably be proved, and any attempt to exclude one in favour of the other is bound to fail. The protein poison or anaphylatoxin is easily made by digesting normal serum with certain substances, as, for instance, agar, and as all the agar is recoverable, it is clear that the matrix of the poison is in the serum itself. When injected into the blood, anaphylatoxin quickly produces the symptoms of the anaphylactic shock; and the agar sol itself also, when injected in small quantity into the blood, produces identical symptoms. According to Bordet the agar acts by adsorbing some constituent from the serum which leaves it in a poisonous condition—i.e., containing anaphylatoxin. In anaphylactic shock, the antigen-antibody complex in like manner adsorbs this constituent from the blood or the cellular elements of the tissues. When immunisation or desensitisation is effected, a substance is produced which protects against the further action of the anaphylatoxin. We may call this substance anti-anaphylatoxin.

Cellular Reaction in Anaphylaxis.

Great importance was attributed by Weil to the cellular reaction in anaphylaxis, and he devised many ingenious experiments proving his contention. Dale further elaborated this point, and has consistently endeavoured to fortify the view that the shock is exclusively a cellular phenomenon, which, though imitated by the anaphylatoxin shock, is nevertheless of a different order. He believes, with Weil, that the antibody is precipitin which on uniting with the antigen produces a precipitate on or in the tissue cells, the resulting "colloidal disturbance" (aggregation)

sufficing to cause the shock, without the production of any particular poison. The somewhat paradoxical position is also maintained that when precipitin is present in considerable amount in the blood, it neutralises the antigen quietly, so preventing its access to the precipitin in the cells. When the circulating antibodies are reduced below a certain amount by their migration to the cells, shock occurs. Dale and Kellaway,⁹ however, working with starch, agar (non-protein substances) and agar anaphylatoxin, obtained some very puzzling results. They found that the chief difference in guinea-pigs between anaphylactic shock and anaphylatoxin shock by starch anaphylatoxin or agar sol related to the condition of the blood platelets as regards numbers, aggregation, &c. But when starch anaphylatoxin or agar was injected into the sensitised guinea-pig, it reacted much more sharply than the normal pig, and the resultant shock was in no way distinguishable from specific shock. Now these results would seem to indicate that the discrepancies as regards the blood platelets, &c., were dependent on the degree to which the blood and cells respectively reacted and not to a difference in kind, as in the sensitised animal the cells have undergone a long preparation.

Precipitin Probably not the True Antibody in Anaphylactic Shock.

The practically constant occurrence of precipitin as one of the antibodies in infectious and other antigenic conditions, and its subsidiary rôle in the immunity process, render it improbable that it should form the true antibody in such a highly specialised syndrome as the anaphylactic shock. Weil,¹⁰ for instance, found that the immune animal often contained an amount of circulating precipitin far too small to explain its immunity, and on the other hand, antigen might be present in the circulation together with large amounts of precipitin. Also the anaphylactic antibody does not react with antigen according to the laws of chemical combination, as after partial neutralisation of the antibody, the effective dose of antigen necessary to produce shock is enormously greater than that required by untreated antibody. It is difficult to reconcile this behaviour with the idea of a precipitate. Dale and Kellaway emphasise the fact that in the uterine muscle test, when precipitin is added to the bath, the response to the antigen is inhibited, and also that with anaphylatoxin the response is feeble, except possibly with agar anaphylatoxin. But Weil found that when excess antigen was added to the bath the response was inhibited, and we should hardly expect adventitious anaphylatoxin to produce an effect equal to that resulting from its generation within the cell itself. We also know that the uterine contraction has nothing specific about it, as it is given by histamine, &c., and it varies greatly in relation to the species of animal used, the dosage, ionisation, &c.

The above experiments were confined to guinea-pigs, but in recent experiments by Longcope¹¹ on the white rat it was impossible to produce anaphylactic shock. Neither uterine nor skin reactions were obtainable, nor could guinea-pigs be passively sensitised with the serum. Yet the rats formed abundance of precipitin and the antigen disappeared from the blood when the precipitins had reached their greatest concentration. The rats, however, reacted typically to peptone (anaphylatoxin). Longcope concludes that in this case the anaphylactic antibody cannot be precipitin.

Experiments with Peptone.

In 1921 Dale and Kellaway tried the effect of moderate doses (0.1 g.) of Witte's peptone intravenously in passively sensitised guinea-pigs, and obtained a definite protection against specific shock (unpublished). Dale suggested that the peptone might act by displacing the antibodies from the tissue cells into the blood, thus inhibiting the shock by neutralising the antigen in accordance with his views. But quite recently Kellaway,¹² in some very important experiments, found precisely the opposite to occur. Using

actively sensitised guinea-pigs, he first tried them with fairly large doses intravenously of normal guinea-pig's serum, and found that the antibodies rapidly began to disappear from the blood, and very soon afterwards they began to disappear from the cells as well. In about two hours the antibodies had completely disappeared from both blood and cells when the animal was entirely refractory to the antigen. In two hours more the antibodies had practically all been restored to the cells, but it was over 20 hours before they were restored to the blood, during which interval the sensitiveness had returned. So far, therefore, the "cellular" theory was in evidence. (It may be as well to mention that "disappearance" here simply means lack of response and not that the antibody necessarily migrated or was destroyed.) Kellaway next tried Armour's peptone (No. 2)* in doses of 0.1 to 0.15 g. intravenously, and found it conferred a high degree of protection, the animals withstanding two or three lethal doses of the antigen. But the action of the peptone was entirely different from that of the serum. It reduced the circulating antibodies to about one-third, while it left the cellular antibody entirely untouched. This is a very remarkable result, and proves that the peptone endowed the body with a protective substance or quality and the inference is certainly justified that the protection was directed against the anaphylactic poison generated by the antigen-antibody complex) by the production of anti-anaphylatoxin. As regards the effect of normal serum, it is interesting to note that in poisoning by anaphylatoxin, Novy¹³ and De Kruijff on injecting normal serum also found a protective effect.

Colloidal Disturbance.

While the existence of anaphylatoxin is capable of direct proof, the purely physical factor of a colloidal disturbance and its supposed effects pertain to the realm of theory. What do we know of the behaviour of the colloids? The French call this disturbance of the colloidal equilibrium "colloïdoclasia," a term which does duty very much after the manner of the blessed word "Mesopotamia." The conceptions which have prevailed as to the special behaviour of colloids as apart from crystalloids have recently been subjected to very drastic treatment in a remarkable work by Loeb,¹⁴ which, on account of its importance and the attention it is receiving, may be briefly mentioned. Loeb endeavours to prove that proteins form ionisable salts with acids and alkalies according to the stoichiometrical laws of crystalloid chemistry.† Protein being amphoteric, it behaves as a base when the H-ion concentration of the solution is above a certain value and as an acid when below that value, while at the critical value, the protein is at the iso-electric point and remains practically non-ionised. With the proof of this, the entire colloidal behaviour of protein solutions as to osmotic pressure, electric charges, &c., is solved on the Donnan principle of membrane equilibria, so-called from its discovery, thermodynamically, in 1911 by Prof. F. G. Donnan, F.R.S., of University College, London. That is, when a membrane separates two solutions of electrolytes and the solution on one side contains an ion (in this case a protein ion) which cannot diffuse through the membrane, the final result will be an unequal distribution of the diffusible ions, so giving rise to potential differences and osmotic forces, and also, in the case of gel particles, to variation of swelling, as first suggested on the basis of the Donnan equilibrium by Procter. If now we accept the further view of Loeb that the colloidal particles or micellæ of a protein colloidal solution can be treated or regarded as very small gel particles out of which protein ions cannot diffuse, but into which crystalline ions can, then it follows that the size and surface electric charge, and therefore also the stability—that is, the tendency to remain dispersed or to aggregate—of the protein colloidal particles will be determined by the unequal distribution of the ions

* At the writer's suggestion.

† Dixon Mann in 1902 contended that proteins behaved like electrolytes (Physiol. Histol., p. 48).

previously referred to. There seems little doubt that the hard-and-fast line between colloids and electrolytes has been to a certain extent removed by Loeb's observations and proofs, and that "colloidal disturbance" involves equally important electrolytic factors. If colloidal disturbances were alone sufficient to cause violent poisoning effects, we should expect these effects to be much more frequent in the course of most diseases.

The Allergic State.

The basal fact in allergy or sensitisation is an innate defect or disposition of the tissues concerned, expressed as an abnormal reactivity. This disposition is transmitted; even though appearing late in life there is no sure ground for believing that it is acquired. Thus, one groom in 1000 may ultimately become horse-sensitive, or one baker in 1000 wheat-sensitive, because an inherent dormant disposition has been activated. Once activated, this labile state of the tissues tends to increase; nor could the permanent removal of the exciting factors ever abolish it, though in young persons the sensitisation may weaken as growth proceeds. In such, the skin reactions may be seen to lessen year by year, and the general symptoms may abate or cease, at least for a time. Some weighty considerations regarding the unlikelihood of sensitisation being acquired are presented by Rolleston.¹⁶

In the allergies—hay fever, asthma, migraine, epilepsy, urticaria and other skin conditions—it is hardly correct to say that the patient is, or has become, sensitised by a "foreign" protein inhaled, ingested, or autogenous, as the sensitisation is already present naturally and may to some extent be compared to the zymogen in a cell which remains inactive till the appropriate excitant reaches it. In a sense, the foreign substance may be said to sensitise, but activation or excitation are the more correct expressions. This is further borne out by the fact that when a cell is naturally sensitised, it can, as a rule, be activated by many different substances, both antigenic and non-antigenic.

Some American observers consider that, as in allergy, the effect of partial neutralisation of antibody is not in evidence, and also, that as complete desensitisation with repeated doses of antigen, as in artificial anaphylaxis, does not take place, the reaction cannot be due to antibodies in the cells. But it is legitimate to consider that if the antibody is autogenous, its quick replacement might occur, and the antigen might even stimulate its production. Besides, many observers have reported passive sensitisation with the serum of allergic subjects. On the other hand, in multi-sensitisation it is difficult to believe that the cells contain separate natural antibodies for each protein. The fact that many non-protein substances (histamine, drugs, &c.) may give skin reactions which superficially are indistinguishable from those produced by proteins, further complicates the issues. In certain other conditions, such as dermatitis venenata, the irritant seems to exert its action solely on the skin, and the reaction seems to increase with successive exposures to the irritant, and as age advances. Conflicting statements have been made as to the exhaustibility of the dermal reaction as between proteins and non-proteins (Mackenzie and Baldwin,¹⁶ Cooke¹⁷). Apparently the common factor, as in anaphylactic reactions generally, is a non-specific poison affecting the capillary endothelium, which varies in intensity according to the nature of the irritant, the reactivity of the skin, and the modifying conditions dependent on the presence or absence of a more or less general sensitisation.

The enormous output of American work on the skin tests within recent years has gone to show that reactions to pollens and the animal epithelia are fairly reliable indicators of a sensitiveness which is more or less general, but that as regards foods, there is no rule in the readings. Multi-sensitisation nearly always occurs, to proteins in entirely different groups. It is evident that the entire substance as used in the test may be so altered by the digestive juices as to

render it innocuous; while, on the other hand, the skin test may be negative and yet constitutional symptoms are produced on ingestion. Out of 939 cases investigated by Rackemann,¹⁸ in only 13 were food tests important or of use in treatment, and in only a very small number, chiefly in children, was benefit derived by withdrawing the particular food from the diet. Apparently in some cases, the food allergen may be absorbed by the mouth. According to the tables of Baker¹⁹ and of Peshkin and Rost,²⁰ at least 10 per cent. of normal children give dermal reactions to proteins. Possibly in the majority of these the hypersensitiveness is limited to the skin.

It is commonly believed that in cases traceable to foods the ingested protein must pass unchanged through the intestinal wall. Excepting possibly the case of infants with disordered digestion, there is no proof of such a leakage, nor is it a necessary assumption since (as in the case of the sensitised animal) activation is possible with all sorts of substances. Thus, an asthmatic attack can often be induced by such substances as peptone or histamine. Is it not possible that the symptoms may be produced by a constituent or disturbance of the food which acts similarly to an urticaria-producing drug? Why should the leak admit one protein only? It has even been asserted (Shannon²¹) that the sucking child may suffer from the effects of a protein which the mother has taken in excess, and which has found its way into the breast-milk, and that guinea-pigs sensitised to the fed protein will react anaphylactically to the milk as compared with normal controls. Now, in the first place, physiology teaches that the transformation of food protein into milk protein is governed by the same laws as apply to growth, the milk protein being built up of amino-acids (McCollum²²). In the next place it has been shown by Hartwell²³ that an excess protein diet in the nursing rat causes a poisonous state of the milk, producing spasms and often death in the young. However this poisonous quality is acquired, it might cause anaphylactoid symptoms in the sensitised animals. In any case the controls in experiments with milk ought to be animals sensitised to a different protein than that fed to the mother, as doubtless they would react to the milk injection in the same manner.†

It is a curious circumstance that the more severe cases of asthma, at least in adults, very rarely give dermal reactions, while the great majority of asthmatic adults are also negative. Also, as in any case dermal reagents form but a fraction of the possible excitants (of the attack), we must regard the excitants as being mainly autogenous, some metabolic product, either faulty in itself, or inadequately reduced. This is occasionally in evidence as the poisonous products resulting from endocrine and ovarian disturbances which appear competent to induce epileptiform attacks, asthma, and migraine; cures having been effected by the administration of thyroid, ovarian substance, &c. (Asche,²⁴ Ross,²⁵ and others). Some curious examples of auto-excitation are recorded by Whitfield.²⁶ Amongst the allergies, it is particularly noticeable in asthma that great variations are encountered in respect of the reactivity to proteins, the symptoms, course, and the results of treatment. We must regard these variations as mainly due to individual peculiarities. This was even found in guinea-pig experiments with peptone by Novy and De Kruif, a dose which was fatal to some animals being without effect in others, while the coagulation-time, blood pressure, &c., showed great variations "due to inherent or developed factors in the given individual."

The Treatment: With Illustrative Cases.

In the clinical examination special attention is needed to the teeth, nasal cavities, tonsils, or other possible sources of infection; to the state of the lungs, the circulation, and digestion; to the presence of the rheumatic or gouty diathesis; and to endocrine defect. Great difficulty is sometimes encountered with nasal

† Since this was written Shannon's results have been directly challenged in experiments by Stuart (Amer. Jour. Child. Dis., 1923, vol. xxv., No. 2, p. 135).

affections, disease of turbinals, polypi, &c., as operations are sometimes inimical or make the asthma worse. It is better to treat cases urgently requiring such at first, and then to wait some time before beginning the immunisation. As a rule such nasal treatment does not benefit either asthma or hay fever. The skin tests may give valuable information. The patient usually knows what things to avoid; in other cases he does not, but, as by the peptone treatment the sensitiveness to them can usually be overcome, it is often unnecessary to insist on their avoidance, particularly ordinary articles of diet. During the treatment the diet should be plain, very moderate, and diuresis encouraged by drinking water or soda water.

In cases where dermal reactions to proteins are given the peptone acts more rapidly and often more effectually. It is a curious circumstance that after the constitutional symptoms have subsided, these reactions persist. This peculiarity is confined to the skin. Otherwise, the desensitising effect of peptone is universal, and includes bacterial intoxication. Dr. Warren Crowe, of Harrogate, has informed me that in certain rheumatic subjects extremely sensitive to bacterial vaccines, a preliminary course of peptone renders them tolerant. The sensitiveness produced by bacterial intoxication has recently been well elucidated by Pratt-Johnson.²⁷ Asthmatic subjects are often highly sensitive to vaccines, including tuberculin, and the symptoms may be greatly intensified by them. This is due to the abnormal reactivity which the sensitised individual exhibits to protein poisons in general. The experience of van Leeuwen² with tuberculin is a case in point, and does not necessarily imply a special sensitiveness to that particular substance. When a specific organism is definitely producing the toxic protein causing the asthma, either directly or indirectly, treatment with the organism should succeed. But such cases are few, and in general vaccines act non-specifically. Dr. Rackemann, who has had a very extensive experience with them, particularly the autogenous variety, tells me that he is compelled to regard their action as non-specific. Experiments are needed to assist in elucidating the matter. The more one sees of asthma, the less one connects it with bacteria.

The Armour peptone, which gave such good experimental results, has for a long time been recommended by the writer for general clinical use, as its proteose content is adequate and it is free from histamine and non-irritant. Most other peptones are deficient in proteoses. Witte's peptone contains histamine and its proteoses are rather toxic. Hence, though very valuable in certain circumstances and cases, it must be employed with great caution. It can be detoxified, however, by a simple process, and yields a useful product which shall shortly be alluded to. Peptones made from vegetable proteins are also valuable aids in certain cases. The peptone solution should always be given either intravenously or intramuscularly, the latter method being appropriate in children and weak elderly persons. The hypodermic method is not only less efficacious, but is open to the fatal objection that it is impossible to adjust the dosage. Only by the intravenous method can such be done, or accurate reactions (if desired) obtained. Intramuscular injections often succeed when given by rule of thumb, but if the case is not satisfactorily responding, the intravenous method should be substituted.

Some illustrations of the treatment may now be given, it being understood that the Armour peptone has been used, unless otherwise stated. A 5 per cent. solution in physiologic saline is used for intravenous use, and a 7.5 per cent. solution for intramuscular use. They must be very carefully prepared and sterilised by heating up to 60°-65° C. and then made faintly alkaline by soda or borax, the latter acting also as a preservative; otherwise 0.5 per cent. phenol is used. The injection is given slowly to avoid reactions, and it is never given during the attacks. Dosage 0.3 c.cm., increasing by 0.2 c.cm. up to 1.5 c.cm. or over.

CASE 1.—Male aged 14. Asthma since 18 months old. Has also had eczema and symptoms of hay fever from time to time. Father, paternal grandmother, and an aunt had asthma; a sister also has asthma. The attacks last a few days, then there is more or less freedom for a week or two, except at nights. Turbinals cauterised four years ago without benefit to the asthma. Is horse-sensitive, and gets violently sick on eating a soft-boiled egg, but can eat one hard-boiled. Is otherwise healthy and well grown. His dermal reactions gave horse-hair 1.5 cm.; egg 1 cm., egg-peptone negative; pollen negative. He got 11 intravenous injections of peptone, beginning with 0.3 c.cm. and increasing by 0.2 c.cm. twice a week up to 1.5 c.cm., no constitutional reactions being produced. The asthma ceased after the fifth injection, and no relapse occurred. In eight months he reported himself quite well, but the skin tests remained though less marked. Then after ten months he reported; he had remained perfectly well and found some time ago that he could eat soft eggs with impunity. The dermal reaction at this time to egg was still 0.7 cm., and irregular; horse-hair 1.3 cm. with spikes; no asthma on proximity to horses.

This case is typical of many, especially in young persons, in which peptone acts as specifically as anything in medicine (in the therapeutic sense) and that whether skin reactions be present or not. Children giving reactions to cat hair, rabbit hair, and feathers have been desensitised without removing the animals; in other cases when the animals were removed, the asthma was unaffected but yielded to the peptone. Ratner²⁸ in eight cases of rabbit sensitiveness found that rabbit hair extract in every dilution aggravated the symptoms, instead of desensitising. Note in the above case that when the mucosa of the stomach could tolerate soft-boiled eggs, yet the skin reaction persisted.

CASE 2.—Female aged 28. About six years ago she went to Johannesburg where the dust apparently brought on sneezing attacks. Several of her nearest relatives suffered from hay fever and asthma. Returning home she underwent several operations on the nose in 1918 at the hands of Sir StClair Thomson without much relief to the symptoms. In the autumn of 1921 the sneezing attacks were so violent and prolonged, continuing for hours, that her condition became alarming. Skin tests negative. She received 15 peptone injections intramuscularly from her own doctor and since then the attacks have entirely ceased.

Whatever the irritant which inaugurated the sneezing attacks the sensitiveness was constitutional and doubtless reacted to various inhalants. Hay fever cases often do extremely well on peptone often when given intramuscularly; nor need it always be given in advance, as the active symptoms yield.

CASE 3.—Female aged 45. Severe attacks of migraine since 14 years. Father had asthma; mother had migraine. The attacks come once a fortnight or once a month, practically always at the menstrual periods. First headache, soon followed by violent sickness for 24 hours. When the sickness ceases the pain locates itself on a small area in the left temple and goes on another 24 hours. Otherwise strong and healthy. Diet has no influence on the attacks. In this case the injections were given weekly. The first effect (after three injections) was to abolish the sickness and the pain shifted to the right temple, quite a new experience. Then a month elapsed without any attack. She had occasional headaches of a neuralgic character during the next two months, but nothing compared with her former previous life of martyrdom. She received 12 injections without the production of any reaction. Her condition remains highly satisfactory.

Migraine is common in women, especially at or near the menses, but also intermenstrual attacks occur. The treatment may stop them at least for a time or it may only stop the intermenstrual attacks. Absence of worry and an easy open-air life are invaluable aids to a cure. Certain cases of epilepsy also respond extremely well to the peptone injections.

CASE 4.—Male aged 55. Three years ago catarrh and suffocative spasms severe in character came on during the night, with profuse glairy expectoration. For a time he was confined to bed. Latterly the attacks came by day as well, rendering him practically an invalid. He had had the best medical advice and many remedies had been tried but to no success. Adrenalin was without any effect. He was recommended by Dr. F. Heasman, of Boscombe, for the peptone treatment. After the first injection he had good nights, and after the second the asthma had entirely

vanished. He received 12 injections in all as a precautionary measure, no reaction being produced by any of them. Some time afterwards he had some nocturnal wheezing but not such as to necessitate further treatment.

Although the treatment acts very promptly in many cases, it is not often that it does so in such a dramatic fashion as in this case; so as a set-off to it, take the following:—

CASE 5.—Female aged 36. Anæmic, emaciated, and fragile. Maternal grandfather and mother were asthmatic. She gave the following in her personal history: Typhoid at 14; peritonitis at 19; pelvic cellulitis at 32; influenza in 1919. Asthma began in August, 1920, along with symptoms of hay fever: getting worse. At present the attacks are most violent and frequent, daily and nightly. The chest was not emphysematous, but rhonchi were present. No hay fever symptoms. Skin slightly positive to pollen. The sputum contained many mucous casts of the bronchioles, including spirals, myriads of eosinophiles, and granules, and a long-chain streptococcus. The treatment was carried out intravenously by her doctor in the usual graded doses at first. She was sensitive and gave some marked reactions to the peptone. After two months there was practically no improvement. She was then tried with a compound peptone—that is, one composed of animal and vegetable peptones, and an improvement definitely set in, some weight being gained also. This improvement only lasted six weeks, and the attacks returned as bad as ever. She then had some streptococcus vaccine, but without any benefit.

Here was asthma of a very "malignant" type, and the feeble condition of the patient gave it full rein. The sensitiveness to peptone is hardly surprising, and for such cases a useful preparation to begin with is detoxified Witte's peptone. This is made by agitating the peptone with excess of 97 per cent. alcohol for a minute or two which extracts the histamine and the more toxic moiety of the proteose. After filtration the non-toxic proteose residue is dried and dissolved. This solution can be given intravenously in large quantity without producing reaction, and possesses undoubted desensitising properties. Note in this case that with a marked family predisposition the asthma did not develop until the age of 35. Also the absence of emphysema is noteworthy. The most violent attacks of asthma occur in non-emphysematous subjects, and is related to the fact that in emphysema the air tubes are distended and have largely lost their elasticity, and so the dead space is more capacious and free.

A case resistant to peptone is not always a severe one. In two patients (unrelated) who resided near each other in the same town asthmatic attacks of a moderate character were very troublesome at night. Both patients were quite free of asthma in London, and usually also if away from home. Nevertheless the most careful treatment by peptone failed to remove the nocturnal attacks when they returned home. Some undiscoverable local conditions were at work evidently producing an atypical disorder.

CASE 6.—Female aged 40. "Chesty" since 11. Asthma since 25 off and on. Father, a sister, and a brother asthmatic. Has been getting steadily worse since 1917, and for the past two years is laid up for three to five weeks three or four times annually with "terrific" attacks. Adrenalin makes the symptoms worse and narcotics have to be employed to an extent rather alarming to her medical advisers. These and the strain of the attacks had reduced her to pretty much of a wreck. Some time previously she had been tested for proteins, &c., and received from a physician a vaccine which immediately on use brought on the asthma very severely and so had to be abandoned. She was wasted and haggard-looking. After the first few injections, they were continued by her doctor, and after nine or ten (1.3 c.cm.) there was a slight yet definite all-round improvement noticeable by her friends and relations. The treatment was persevered in, but latterly began to upset her, even in moderate doses, causing headache, severe pains in the limbs, and some rise of temperature. The dose had to be gradually reduced to about 0.5 c.cm. and the compound peptone was substituted for the ordinary. Her sensitiveness to the peptone increased so that she reacted to 0.3–0.4 c.cm. even when diluted with saline, and her doctor who carried out the treatment with the greatest care had considerable difficulty in adjusting the dosage. Nevertheless, a great improvement was steadily

going on; and the asthma had practically ceased, while the general health was being restored. The treatment was continued by five- to eight-day inoculations for several months. Eighteen months have elapsed, and the patient remains well and is delighted to be able to take country rides on horseback.

When peptone is administered over a very long period, it is usually better tolerated, at least for a time, but a few cases get hypersensitive, which, however, is not a drawback. Note in this case may also be made of the severe pains following the injections. These are often encountered in rheumatic or gouty subjects owing to the increased katabolism which peptone produces. In one case, in addition to severe body pains, a number of subcutaneous nodules appeared over the scalp.

CASES 7 and 8.—These may be taken in conjunction, as they illustrate certain features in common, particularly the successful result of prolonged treatment, and the tolerance of large doses. Male, aged 44, had suffered from asthma for eight years. Mother was asthmatic. Attacks occurred almost nightly and it was brought on by any exertion during the day. He was also subject to attacks of bronchitis attended with much expectoration, but he did not connect these specially with the asthma. His doctor had given him autogenous vaccine prophylactically, apparently with benefit. Health otherwise very good. He was free of bronchitis but suffering from asthma when the peptone treatment was begun. After nine injections the asthma had practically gone, when unfortunately he had a severe bronchitic attack which laid him up for several weeks. The asthma also gradually developed and had become as bad as ever when the bronchitic attack was over. The peptone treatment was resumed, and given every four days and then weekly for three months, the dosage rising to 3 c.cm. without producing any reaction, apart from the slight leucocytosis which always follows. During this time, the asthma had entirely gone, and for the past seven months he has been quite free from symptoms.

The other case, female, aged 55, had also suffered for eight years. Very severe attacks every three or four weeks lasting two to three days; adrenalin gives relief for a few hours, then the attack recommences. Family history negative. Never quite free between the attacks. Treatment by peptone was begun, but during the fourth week an attack supervened as usual. When quite better the treatment was recommenced with small doses, and the dosage gradually worked up to 3–4 c.cm. so as to produce a mild reaction, giving a rise of temperature after a few hours of about 1.4° F. These latter doses were given weekly, and the peptone was combined with either a small quantity of Witte's peptone or else a peptone made from wheat of rather an active character. During the four months she was under treatment, there was only one slight attack of asthma. Six months afterwards she wrote stating that she remained perfectly well.

In these two cases the prolonged treatment ultimately subdued the asthma, and large doses were tolerated. Sometimes in men one finds temporary sexual disability under these conditions. The reactions were produced in Case 8, as elderly and stubborn cases often need a fillip. In general, also, if after a number of non-reactive doses, improvement is unsatisfactory, mild reactions must be induced when a rapid improvement may ensue. When, as in this case, an attack occurs during the treatment, one must wait until recovery is complete, and then begin again with a very small dose, as the result of the attack is to produce the protective substance, anti-anaphylatoxin. Anti-anaphylatoxin is also produced by a single big dose of peptone, but the protection is fleeting. On the other hand, the gradual immunisation by small doses creates in addition that disorientation of the sensitised tissues towards the exciting agents which renders their attacks abortive for a longer or shorter time, according to the nature of the case.

A CASE OF EROSION OF THE RECTUM BY AN ECTOPIC PLACENTA.

By J. A. CAIRNS FORSYTH, M.Sc., M.B.,
CH.B. LEEDS, F.R.C.S. ENG.,

SURGEON TO THE FRENCH HOSPITAL; SURGEON TO OUT-PATIENTS,
ROYAL WATERLOO HOSPITAL, LONDON.

EROSION of a hollow viscus by an ectopic placenta is fortunately an extremely rare occurrence, for the consequences may be very serious. The case here recorded was remarkable in that severe hæmorrhage from the rectum was one of the initial symptoms of ectopic pregnancy.

History.—The patient, a married woman, aged 34, bipara, was admitted to the French Hospital under Dr. Septimus Sunderland on account of intermittent griping pain in the lower abdomen, constipation, and severe pain in the rectum during defæcation. The past medical history was negative, except that after the birth of her second child, eight years before, the patient had been very ill from pelvic peritonitis and was kept in bed for five months. When convalescent she was cured at Liège and became pregnant some few months after, but the pregnancy ended in abortion. There had been two miscarriages before the birth of the second child.

The present illness commenced three weeks before admission with a sudden attack of colicky pain in the hypogastrium. The pain was so acute that the patient had to rest in bed for a few days and, on getting up, it returned with increasing severity. Obstinate constipation supervened, and with it intense pain in the rectum, causing a false desire to go to stool. Without the help of enemata the bowels refused to act, and when they did the agony was excruciating. At no time during the present illness had any blood or pus been passed per rectum. On being questioned, the patient stated that on the sixteenth and fifteenth days before admission there had been some blood-stained vaginal discharge, but this she regarded as her normal monthly loss, although it was much less than usual. Previous to this the periods had been regular and normal.

Condition on Examination.—The abdomen was flat and soft and moved freely on respiration. A hard swelling about the size of an orange could be felt projecting above the pubes. It was slightly mobile and not tender. Per vaginam, the cervix was found to be high and tightly pressed against the symphysis. The posterior fornix was bulging from the presence of a hard rounded swelling which, per rectum, appeared to be about the size of an egg. No fluctuating point could be detected.

Three days after admission the patient had a severe hæmorrhage from the bowel and became very pale and collapsed. Dr. Sunderland asked me to see her as he had found in the bulging wall of the rectum, just within reach of the finger, an umbilicated depression about the size of a sixpence. Further examination showed that the depression had a sharp, clean-cut edge, and that it extended through all the coats of the rectal wall. The base appeared to be formed by the tumour in the pouch of Douglas. We discussed the possible causes of the condition and decided that most probably the case was one of ruptured tubal gestation with erosion of the rectum by the placental trophoblast. I arranged to make a direct examination of the rectum with the sigmoidoscope, but before this could be done the patient had another attack of hæmorrhage and

looked as if she were going to die from loss of blood. Immediate operation was decided on.

Operation.—When the abdomen was opened no free blood was found. The suprapubic swelling proved to be the fundus uteri, occupied by a fibroid the size of the closed fist. Signs of old inflammatory trouble were evident in the left tube, which was converted into a small retort-shaped hydrosalpinx, and in the left ovary, which was firmly embedded in the mesosigmoid. The right tube turned sharply down behind the uterus and entered Douglas's pouch, the mouth of which was closed by adhesions. These were separated and the tube traced downwards; it was found to terminate in a ruptured tubal gestation. In order to get better exposure the uterus, with the left tube and ovary, was quickly removed by subtotal hysterectomy. The right tube with the adherent mole were then easily shelled out, care being taken not to enlarge the opening in the rectum. No blood or pus was found in Douglas's pouch. An attempt was made to suture the opening in the rectum, but as that proved impossible the posterior fornix was incised from above and a large drainage-tube passed into the vagina. The mouth of Douglas's pouch was then closed by a purse-string suture, and reinforced by stitching the anterior peritoneal flap made in removing the uterus to the rectal wall above. By now the condition of the patient was far from good, so it was decided not to spend even a few minutes more in performing a temporary colotomy. The patient was put back to bed and kept under morphia; in two days she had improved sufficiently to permit of the colostomy being done.

Examination of Parts Removed.—The ectopic gestation had evidently occurred in the ampullary end of the tube, and the gestation sac had been extruded by tubal abortion rather than by tubal rupture, for the ostium, although expanded, was intact, except for a small tear in its upper edge. Part of the mole remained within the cornucopia-like end of the tube. Dissection of the mole revealed a small amniotic cavity containing the crushed remains of a tiny foetus a few millimetres long.

After History.—The patient passed through a stormy time during the first week, for although there was free drainage from the vagina, signs of pelvic peritonitis developed. The pulse became quick and feeble, and the whole aspect of the patient denoted toxæmia. Fortunately there was no intestinal paresis, and the colostomy acted well from the start. About the seventh day the patient began to improve and was able to get up on the twenty-first day. The colostomy was closed on the fifty-ninth day, the aperture in the rectum having healed soundly. When viewed with the sigmoidoscope a small white scar was all that remained to show where the erosion had taken place. The patient left the hospital in excellent health a fortnight later.

Remarks.

Search in the literature shows that very few similar cases have been recorded, and I have been unable to find an exact duplicate. In a paper read before the Section of Obstetrics and Gynæcology of the New York Academy of Medicine,¹ H. C. Chase described the case of a patient of 25, in whom three months' amenorrhœa was followed during six weeks by painless hæmorrhage, and subsequently by vomiting and hypogastric pain which continued for 17 days. At this juncture the pain diminished, but a large amount of dark clotted and bright red blood was passed per rectum. At the time of her admission to hospital, in a state of grave anæmia and collapse, examination was negative except for a mass the size of the fist in the right side of the pelvis. At operation the cæcum was adherent to the posterior surface of a ruptured right tubal gestation, and, when it was separated, a hole in the bowel wall, a little larger than half-a-crown, was seen. The cæcum contained clot and the entire foetus. There was no free blood in the abdominal cavity. The rent in the cæcum was repaired, the ectopic mass removed, and a drain placed in the posterior fornix. The patient made a good recovery. At the same meeting, Vineberg related a case where an ectopic pregnancy formed in the small stump of the tube left after salpingectomy for pyosalpinx some time before. The ovarian sac was bounded in part by a portion of the sigmoid. Hæmorrhage from the bowel had occurred, but at operation he could not find any opening in the intestine. Evidently the villi had eroded the wall of the sigmoid sufficiently to produce bleeding but not enough to cause a defect perceptible to the naked eye.

TREATMENT OF THE FLAIL ELBOW-JOINT

WITH A NEW OPERATION OF ARTHRODESIS.

By WALTER MERCER, F.R.C.S. EDIN.,

SURGEON, CRAIGLEITH HOSPITAL; TUTOR IN CLINICAL SURGERY,
ROYAL INFIRMARY; MEDICAL SUPERINTENDENT, TYNECASTLE
ORTHOPÆDIC CLINIC, EDINBURGH.

THE complete flail elbow is not a very rare condition; in my own experience, during the year before this article was written, I have seen six complete and upwards of a score of partial flail joints. The complete flail joint is one in which the patient has absolutely no control over movement and in which there is mobility in all directions. In many cases, particularly following operative treatment, the forearm may sometimes be rotated a complete turn of 360° on the upper arm, there being no bony or cartilaginous connexion between the two. In the partial flail cases there is some apposition between the bone ends, and the muscles are sufficiently preserved to exert some leverage.

Causes.

The great majority of such cases at the present time result from gunshot wounds, which have been treated, usually in the Front areas, by excision of the wounds and bony fragments. In most cases sepsis following wounds has further militated against the preservation of function; in a few cases it has occurred after too generous excision of a tuberculous joint, whilst in rare instances a flail elbow is seen resulting from paralysis of the muscles acting on the joint. In these cases, however, the joint surfaces are preserved, and the treatment is to some extent simpler.

Many of the cases, particularly those following operative treatment, are further complicated by nerve injury, most commonly of the ulnar nerve, but in one case referred to below the radial nerve was completely severed, greatly increasing the disability. One case had been treated by an extension applied to the arm through the fingers, which had so stiffened up that grip was much impaired.

Influence of Occupation on Treatment.

In consideration of treatment of a flail elbow the patient's occupation is of the utmost importance; he may require a strong stable joint, or a moveable joint which, although weak, may be brought under some control by operation or the use of apparatus. The arm has also to be considered; in a right-handed person a strong left elbow-joint is probably of less importance than a movable one. Not only the patient's occupation, but also his other pursuits must be ascertained; in a recent case I had decided on occupational grounds to perform an arthrodesis, when the patient remarked that his principal amusement was violin playing; this was a left elbow-joint, but his playing made it important to retain movement of the fingers up and down the strings in a "creeping" method which would, of course, have been impossible with an arthrodesis.

Treatment.

Before any definite decision is made concerning the patient's future I consider it important that he should have a course of at least six weeks of physio-therapeutic treatment, the arm being carried in a sling in order to shorten the flexors of the elbow-joint. Even better than the sling would be a light plaster case bivalved and removed daily for treatment, which would consist of massage, active and passive movements, but particularly active exercises, principally in the direction of flexion, and faradism to the muscles acting on the elbow-joint. Such a course of treatment can make a vast difference to apparently hopelessly flail cases. After the utmost has been got out of the joint by these means the possibility of controlling the joint by some appliance, or the necessity of operation, must be considered. If the

man has any power of flexion in the joint there seems no doubt that some sort of appliance is preferable; of the appliances on the market I particularly recommend two—the Mackay flail-elbow appliance and Young's flail-elbow appliance. If there is no power of flexion, even although the joint is supported, the Mackay appliance is the better, because by an "elbow flexion cord" taken to harness on the opposite shoulder the man can get a certain amount of flexion by forward movements of this shoulder. He can also lock the joint in any position. If the patient has any power of flexion Young's appliance is very satisfactory; with this the man can bring the arm up to a flexed position and retain it by a simple automatic catch, on release of which catch the elbow-joint is again freed. The joint can also be permanently locked at any desired position. The drawback to both these appliances is that there is no control over the forearm movements; the forearm is usually completely supinated and cannot be altered. Further, there is great difficulty in preventing the appliance slipping down the arm in such a manner that the flail joint and the appliance joint do not act on the same plane. If stability is required, however, and particularly if the appliance is found to be cumbersome and uncomfortable, some operative treatment is indicated.

Choice of Operation.

We have a choice between five operations, some of which are mentioned only to be condemned:—

1. Silk ligaments have been used, being threaded through the humerus and through the ulna to keep the joint in a position of flexion.

2. In the same way fascial transplants from the fascia lata of the thigh have been used. I have no experience of these operations, but they seem of doubtful utility, the joints still being flail to a considerable extent afterwards.

3. Sir Robert Jones recommended a plastic operation on the skin; he removes a diamond-shaped area from the front of the joint and stitches it up transversely to keep the joint flexed. This, I feel sure, is now given up, as the stretching of the skin gives a bad end-result.

4. Goetze's method is simple and to some extent efficient, but it necessitates the use of a complete supporting apparatus. This operation consists of freeing of the lower arm extensors and flexors and their transplantation. After a short time the free working muscles become so strengthened that function of the joint is obtained by use of the Goetze apparatus. A certain amount of pronation and supination is also stated to be possible with this apparatus.

5. Probably by far the most preferable operation is arthrodesis. Previous to the operation I am about to describe I have not seen a successful result from arthrodesis; the elbow is admittedly not an easy joint to deal with, but I am sure that most of the bad results are due to badly-planned operations. Too much has hitherto been expected of the joint in the devitalised state of its bony fragments and the poor immobility given by previous operations. The adjoining surfaces of the radius and ulna have been bared in wedge-shaped fashion and the humerus similarly bared and wedged between the ends of the forearm bones. Even with wiring no stability resulted from this union; ankylosis must have been very rare and had never occurred in any case I saw. Having little faith in this operation, I never performed it; it seemed to me, however, that if the flail elbow resulting from excision—particularly where the lower end of the humerus had been removed—was treated rationally the patient could almost be promised a complete arthrodesis. The operation which I devised and now perform in this type of case is as follows.

Technique.

Access to the joint is obtained by a median posterior incision; particular care is taken of the nerves, especially the ulnar nerve on the inner side; two skin flaps are reflected well forwards and the triceps is

stripped upwards. The forearm muscles are then freed from the bone, but the periosteum is left attached. The lower sclerosed end of the humerus (usually about $\frac{3}{4}$ inch of bone) is then completely removed; the periosteum above this is raised in a cuff leaving the bone bare. The bone is next filed into a complete square with an ordinary rough file. The position of ankylosis is next decided. It is not, of course, possible to give the desired position absolutely, but with a certain amount of trouble some pronation or supination can be obtained. The forearm bones are then dealt with. It is usually found that the two bones are ankylosed at their upper ends, either by bone formation or by strong fibrous tissue. This is preserved as far as possible, particu-

it is found that a very good firm apposition is got. The cuff of periosteum, usually split in two or three places longitudinally, is brought down and stitched over the line of union, so helping bone formation in the part of greatest need. It is now important to get a good muscle covering for the ends of the bone. This is usually obtained without much difficulty, the triceps being particularly useful. The skin is sewn with silkworm gut without drainage, and a plaster cast applied over all, to include shoulder, wrist, and chest. This is retained for three months at the end of which time it is taken down, the stitches are removed, and a small cast, including arm and forearm, put on for six weeks. A sling is applied after the small plaster has been removed and daily physio-

FIG. 4.

CASE 2.—Lower end of humerus gone and remainder sclerosed. Greater part of olecranon removed. Some ankylosis between radius and ulna.

FIG. 3.

CASE 1.—Showing the result 14 months after complete bony ankylosis, with good new formation of bone by the separated periosteum.

FIG. 5.

CASE 2.—X ray taken ten months after operation showing the complete ankylosis with much new bone formation. Wire is brought round in front of the joint and knotted at the side.

larly while the bones are being sawn. A square hole (see Fig. 1) is now sawn as near as possible to the ends of the bones, the square fitting the already similarly-shaped humerus. A small fine frame saw, with detachable blade, is the most useful for this purpose. The humerus is then fitted into the square and a bone drill used to perforate a hole from side to side of the two forearm bones through the end of the humerus. Stout silver wire is passed through this hole and tied, with the knot in front of the joint.

This position of the wire precludes pressure on the skin and consequent irritation. Behind there is not a great amount of muscle to cover the wire, but in front of the joint it is deeply buried. The ends of the forearm bones are bevelled as much as possible to prevent any projection. When the wire is in position

therapeutic treatment started, massage and faradism being used to get the muscles into condition, and ionic medication with calcium to strengthen the callus.

CASE 1 (Figs. 2 and 3).—A man, aged 25, wounded through the right elbow-joint in March, 1918. Wounds excised at the base in France, and he was discharged from

hospital in April, 1919, following prolonged sepsis. At the end of 1919 an attempt at arthrodesis performed. Admitted to my care in April, 1920, because of the "uselessness of his arm." On examination the elbow-joint was practically completely flail; only a few degrees of voluntary flexion possible from the extended position. No power of extension. Forearm could be rotated through a half-circle on the arm. Extensive scarring round the elbow-joint. Patient had worn a supporting apparatus, but found it impossible to carry on his work as a labourer. There was a further complication, a complete musculo-spiral nerve lesion below the origin of the triceps branches. X ray showed that the whole of the lower end of the humerus and the greater part of the olecranon had gone. There was much new bone around the ends of the ulna and radius. The bone ends were fairly healthy in appearance. In a right-handed labourer a strong right elbow-joint with the angle greater than a right angle, about 110° , and the forearm in the supinated position is preferable. The tendon transplantation for the nerve injury was deferred until the bones were stabilised to give better leverage. It was decided, therefore, to perform arthrodesis.

Operation.—The operation on May 5th, 1920, was exactly as described above, except that the wire was knotted behind the joint. A good covering of muscle was obtained. Before the plaster cast was applied the joint was beautifully firm, and this position was retained without difficulty while applying the plaster.

On July 25th the plaster and stitches were removed; wound completely healed, joint feels firmly ankylosed. Light plaster case applied, and removed in its turn on Sept. 8th. The joint was firm; light massage and faradism, calcium ionisation, X rayed. In August, 1921, joint was firmly ankylosed. The patient uses it freely and the muscles are in good order.

CASE 2 (Figs. 4 and 5).—A man, aged 27, wounded in right arm August, 1918. Wounds excised in France; healed up in December, 1918. No further operation. Admitted June, 1920, because of "weakness of arm." On examination the right elbow-joint was flail, with no power of flexion or extension. Ulnar nerve involved in scar, but not completely severed. Only slight scarring of skin, sepsis having apparently been a minor consideration. X ray showed that the whole of the lower end of the humerus had disappeared; the end remaining was somewhat conical, being in apposition to the forearm bones. The olecranon process had also been excised in great part and there was some new bone formation round the ends of the ulna and radius, apparently firmly ankylosing them. The patient was a labourer and found the arm useless to him. He was keenly desirous of having the joint ankylosed.

Operation.—The operation, on July 6th, 1920, was as described. The ankylosing of the forearm bones made immobilisation an easy matter. After fitting and drilling, the terminal portions of the ulna and radius were cut as nearly flush as possible and the insertion of the triceps fixed over them. The ulnar nerve was carefully preserved, no attempt being made to free it from the scar tissue. Convalescence was uninterrupted and in October the large plaster was cut, stitches removed, and a lighter plaster applied after X raying. The patient was discharged from hospital with the joint firmly ankylosed; he is now working and states his arm is "champion." In the spring of 1922 he fell on his ankylosed joint and fractured the lower end of the humerus above the arthrodesis, but it united satisfactorily and is now as firm as ever.

Conclusions.

1. Flail elbow supporting appliances are not satisfactory as a rule; the patient finds them very cumbersome and usually discards them.
2. In most cases an arthrodesis, and in all cases a stable elbow-joint, can be promised, for if bony union does not take place, fibrous union and accurate fitting give an equally good result.
3. The operation is extremely simple; the result is strong, as shown in the case where the humerus was afterwards fractured above the point of old union.
4. The elbow can be fixed at practically any angle, and there is a fair range of choice in fixing the forearm.

ASSOCIATION OF ECONOMIC BIOLOGISTS.—A meeting will be held at 2.30 P.M. on April 27th, in the Botanical Lecture Theatre of the Imperial College of Science, Prince Consort-road, South Kensington, London, S.W., when Dr. C. M. Wenyon will read a paper on Some Recent Observations on Pathogenic Protozoa of Plants and Animals, and a discussion will follow.

CASE OF HYPERTROPHIC PERIPHERAL NEURITIS,

WITH RECOVERY.

BY F. G. HOBSON, D.S.O., M.D. OXF.,
M.R.C.P. LOND.,

HONORARY ASSISTANT PHYSICIAN, RADCLIFFE INFIRMARY
AND COUNTY HOSPITAL, OXFORD.

In 1921 Dr. F. J. Nattrass published¹ an account of a case of recurrent hypertrophic neuritis occurring in a boy aged 18. The following case presents striking similarity in many aspects. The patient, a tailor, aged 42, gave an account of his past history and of his illness as follows, and presented a clinical picture as detailed below, when first seen as an out-patient in May, 1922. He was a distinctly intelligent and observant patient.

Family History.—Nothing of any significance could be ascertained in the case of parents or relations.

Past History.—Prior to 1910 he had suffered from a gastric ulcer for which in that year he underwent an operation, and since the operation he has been practically free from abdominal symptoms. Denies venereal disease. Has only taken alcohol on very rare occasions—practically a teetotaler; smokes very little tobacco; is married, and wife and five children are all in good health.

Present Illness.—On Jan. 20th, 1922, he had an attack of "influenza"—i.e., catarrh of respiratory passages and a temperature—when he took to his bed. His wife and several of his children also presented similar symptoms, and he had to leave his bed before he felt well enough to do so in order to care for them. His wife and children made an uneventful recovery. On his second day in bed he noticed stiffness and pain on the ulnar border of his left hand. The influenzal symptoms cleared up after a week, but the discomfort in the hand persisted, and similar feelings of pain and stiffness commenced in the right hand and in both feet. These symptoms became gradually worse, and were accompanied by increasing weakness of all four limbs and wasting of the muscles. On his private doctor's advice he underwent a course of electrical treatment, which had lasted nine weeks before he presented himself in the out-patient department, and from which he had derived no benefit. His condition had steadily deteriorated, and for the past four weeks he had experienced increasing difficulty in articulating his words and in masticating and swallowing his food. He stated that his hands "felt as large as boxing gloves," and that when reading the paper his vision was unimpaired for a time but gradually became blurred and misty.

Clinical Condition.—He walked with a shuffling weak gait with a distinct element of foot-drop. He had to be undressed, as he was incapable of performing any of the necessary procedures of unbuttoning and removing his garments. He was pale, thin, and generally wasted; none of the thoracic or abdominal viscera presented any evidences of disease.

1. Special senses: (a) Vision—could read ordinary print without difficulty; fields, roughly tested, normal; fundi normal. (b) Hearing unimpaired.

2. Cranial nerves: 1st, not tested; 2nd, as above, pupils equal and react to light and accommodation; 3rd, 4th, and 6th, movements complete, but a rapid nystagmus on looking to the left; 5th, motor weak, sensory unimpaired; 7th, weak; 8th, normal; 9th and 10th, mastication, articulation, and swallowing weak; 12th, tongue protruded straight; no wasting or tremors noted.

3. Sensation: There were disturbances of sensation of the "glove and stocking" distribution as follows. Hands: Complete loss of appreciation of heat and cold, with some blunting of pain sense, over dorsal and palmar aspects of both hands and extending up the forearm for about two inches. Complete loss of sense of position of the fingers and tactile localisation. Calves and feet: Complete loss of appreciation of heat, pain, and cold over sole and dorsum of both feet; failure to appreciate heat and cold also extended upwards to the level of the knee on each side. Complete loss of vibration sense and of sense of position of foot and toes.

Coördination of movements was not specifically examined, since the patient was apraxic as regards both hands and feet by virtue of the muscular wasting and loss of motor control. Over the rest of the body no loss of superficial or deep sensibility could be detected.

4. Motor system: (a) Extreme loss of power in all movements of arms, not quite so marked in lower limbs, and less

¹ Journal of Neurology and Psychopathology, 1921, ii., No. 6, pp. 159-165.

marked above than below the knees; (b) general wasting of all limb muscles, particularly well marked in calves, forearms, and small muscles of the hands—muscles very flaccid; (c) complete loss of all deep and superficial reflexes; (d) fibrillary twitchings well marked and observed on many occasions in biceps, triceps, latissimus dorsi, and gastrocnemii; (e) sphincters not disturbed.

5. The nerve trunks comprising the brachial plexus and the ulnar nerves of each arm appeared to be definitely hypertrophied and somewhat tender when rolled under the fingers. This important point was verified by making numerous comparisons with the nerves of other patients in the ward who were thin and wasted from other causes.

6. Wassermann reaction in blood, negative.

Treatment.

The patient was admitted to the wards and remained an in-patient for ten weeks. During the whole of this period he was given small injections of anti-influenzal vaccine every five days. The mouth was cleansed and all the teeth removed, the bowels regulated, and small quantities of arsenic and nux vomica administered t.d.s. After three weeks' rest in bed, gentle massage of the affected limbs was commenced, and the patient discharged to continue as an out-patient for massage. He was afebrile throughout. From the time that massage was commenced a marked improvement set in, and after attending as an out-patient for six weeks, the patient discharged himself and returned to light work at home. Normal powers of articulation, mastication, and swallowing returned some weeks before the recovery of the power of the limbs.

Re-examination in December, 1922.—The only remaining evidences of the previous disturbance are:—*Objective:* (1) Slight nystagmus, which may have been always present; (2) very slight incoördination of movements of hands; (3) the hypertrophy without tenderness of the palpable nerves and nerve trunks, which is still very marked in spite of the recovery of the limb muscles to the normal proportions. *Subjective:* Only complains of a little stiffness in the movements of the toes of both feet. Examination showed abdominal reflexes and tendon reflexes of lower limbs are present, normal, and equal. Plantar reflex not obtained. Biceps jerks normal and equal, triceps and supinator jerks not obtained. No disturbance of cutaneous sensation could be detected. The power of all limbs is good.

The patient has for the past month been doing 10½ hours a day heavy manual labour as a trimmer's machinist, and pronounces himself as being in every way as well and strong as before his illness. In appearance the patient is of good colour, slightly built, and thin.

Remarks.

The clinical features of especial interest in this case are:—

1. The absence of any definite toxæmia which could account for the widespread and damaging peripheral neuritis. There would seem to be no doubt that the patient experienced no more than an ordinary mild attack of influenza, since his recovery from the catarrhal and general symptoms was complete in one week. At the present date he is inclined to think that he had begun to experience some slight loss of motor power prior to his attack of influenza, but this was insufficient to cause him any apprehension or interfere with his ordinary duties.

2. The widespread fibrillary twitchings noticed over a period of several weeks which suggested some involvement of the anterior horn cells, but must presumably be attributed to damaged motor-nerve fibres in the peripheral nerve in view of the well-established sensory changes.

3. The completeness of the recovery of both motor power and deep and superficial sensibility.

4. The marked hypertrophy of the peripheral nerves and nerve trunks. This last and most important feature was noted by several observers and repeatedly verified by comparison with other individuals.

There would seem to be every reason to regard this case as a parallel to the case reported by Dr. Natrass, who also saw this case prior to his admission to the Radcliffe Infirmary. It is impossible to prognosticate whether there will be a recurrence, but the patient's present strenuous and industrious occupation should be a good criterion of the completeness of his recovery.

I am indebted to Dr. A. G. Gibson, physician to the Radcliffe Infirmary, for permission to publish this case.

Medical Societies.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.

DISCUSSION ON SYPHILIS AND MARRIAGE.

A MEETING of this Society was held at 11, Chandos-street, London, W. 1, on March 23rd, Dr. WILFRID FOX presiding, when a discussion on syphilis and marriage took place.

Dr. AMAND ROUTH opened the debate with an address, which was published in THE LANCET of March 31st.

Dr. FOX said that an interesting point was whether a woman who had had a syphilitic child was herself necessarily syphilitic. The modern view was that she must have syphilis, but he had not been convinced. He quoted a case described by the elder Fournier, in which a woman who had borne a number of congenitally syphilitic children was later impregnated by a healthy man and thereafter gave birth to a healthy child; she subsequently resumed her cohabitation with the syphilitic father and produced congenitally syphilitic children again.

Education as a Means of Attacking the Problem of Syphilis.

Sir JAMES PURVES-STEWART said that on the question of syphilis and marriage there were several different parties to be considered, sometimes with conflicting interests. He believed that the number of individuals who deliberately married, knowing themselves to be in an infective state, was relatively small. What answer should be given by the medical man to the syphilitic individual who wished to marry? Nowadays most syphilologists would agree that if a patient preserved a consistently negative W.R. in the blood for two years, if a provocative W.R. proved negative, and the cerebro-spinal fluid was also negative—permission to marry might be given. provided there were no physical evidences of syphilitic disease. Unfortunately the patient often indulged in promiscuous intercourse during this probation time. The State might conceivably prevent him from marrying, but the real problem was the prevention of such promiscuous intercourse, which constituted a real danger to the State.

The best mode of attacking the syphilitic problem in reference to marriage was by means of education. Firstly, insistence must be made on the intensive education of the medical profession in order to acquire increased skill in the diagnosis and treatment of venereal diseases. Secondly, the lay public, especially young people, must be educated with regard to the dangers of these diseases. One could not expect too much from attempts at educating older persons, but, fortunately, they were less likely to acquire these diseases. The first aim must be to bring about prevention. The ideal thing, from the point of view of the community, would be preventive inoculation against venereal diseases, as against small-pox, enteric fever, tetanus, &c., if it could be attained. It might be a matter of two or three different inoculations. But that idea was not yet practicable. There was not yet available a serum which was dependable as a preventive of syphilis. Failing inoculation, one must fall back upon local preventive measures. Notwithstanding certain disadvantages, which were always being emphasised by the lay press, and still more by the religious press, this prevention by local measures was vastly simpler than the life-long treatment which became necessary after infection had actually occurred. Once a man became syphilitic he required treatment, or at all events observation for the rest of his life. The medical profession had no right to withhold the knowledge of preventive measures from patients. He did not think such knowledge would necessarily produce a wild outburst of sexual promiscuity; but even if it did, this, though

bad enough, would be a lesser evil than the infection of innocent women and future children. Another problem was that of prostitution. Attempts to regulate prostitution or to stamp it out were insufficient, for the majority of cases were infectious from amateurs. The need was, therefore, to see that young men were clearly instructed as to the dangers of venereal disease. Venereal infection, in itself, was no crime; it was only a crime when the sexual connexion at which it was acquired was a misdemeanour. A man might acquire syphilis innocently—e.g., from his wife. In regard to venereal disease, innocence and ignorance were entirely different things. The most expert roué was the one best equipped with adequate means for avoiding disease, while it was the inexperienced youth, probably intoxicated, who usually acquired venereal infection. It was the duty of the profession to prevent venereal disease by every means in their power. By all means let them vigorously preach the desirability of continence in both sexes in unmarried persons; but, so long as human nature remained as at present, it would be a cruel and immoral policy to withhold knowledge concerning preventive measures from any intelligent adolescent or adult.

The Aspects of Infectivity and Life Assurance.

Dr. J. H. SEQUEIRA said that the problem of when it was the duty of the doctor to allow a man who had become infected with syphilis to marry was a most important problem, and one which bristled with difficulties. Certain tests had been laid down but it was a very difficult thing, in a large proportion of cases, to attain to such a test. There was the primary chancre type of case with a negative W.R., which could be rendered non-infective, or indeed cured, by adequate treatment in most cases, such a patient possibly never having had a positive W.R. If such a patient were watched for two years afterwards, and the W.R. remained negative, he could safely be allowed to marry. There was also the type of primary chancre with a positive W.R., and so on, to the stage of generalisation, where it was increasingly difficult to produce a permanently negative W.R. Still, in the larger proportion of such cases a cure could be procured, and the earlier the cases the larger the proportion. To these, it would be agreed, permission could be given to marry. But there was a more difficult type of case, in which the W.R. could never be rendered permanently negative. Members would recollect cases which had been treated more or less intensively for several years, without a permanent negative W.R. being secured. Some such could be possibly rendered non-infective by the administration of thyroid, but not all. As Sir James Purves-Stewart had said, the patient had to be considered from several aspects. There were two aspects from which Dr. Sequeira usually approached a case; one was from the standpoint of infectivity, the other from what might be called the life-assurance point of view, and he quoted the following case to illustrate his point: A young officer became infected during the war and placed himself in the hands of a chemist, who temporarily relieved his symptoms. The patient had no very marked secondary symptoms, but at the end of 18 months he developed complete hemiplegia. The W.R., for both blood and cerebro-spinal fluid, was positive, and he had the abnormal cell count characteristic of cerebro-spinal syphilis. It was believed that the case was of vascular origin, and that intensive treatment would get him well. Under that treatment he had now had, for a considerable time, a permanently negative W.R., his cerebro-spinal fluid was normal, and he was well. He was engaged to be married, and consultations were held between venereal disease experts and the general practitioner as to whether it would be right for him to marry. Dr. Sequeira held that if he were rendered non-infective for a certain period it would be safe for him to marry from the point of view of risk of infection to the wife and any progeny there might be; but that, from the life-assurance point of view, he

was a damaged man, and so his expectation of life could not be said to be so good as if he had not had the disease. That man might, at some remote time, develop some symptoms, but it was necessary to differentiate that possibility from active likelihood of infection of wife and children.

Could a man whose positive W.R. could not be changed by treatment be allowed to marry? He thought there might be too rigid a standard. It was a question of prolonged treatment, and he had advised in cases of this type that at regular periods during married life the patient should undergo treatment, and he had seen normal children from such marriages. The experience of others in such cases would be valuable. Sir Jonathan Hutchinson allowed marriage after only two years of continuous treatment by mercurial pills, and in a large number of cases that course proved safe. Dr. Sequeira had known men who underwent that course and whose families were healthy. He agreed it was important to have a high standard, but in certain circumstances its enforcement was a considerable hardship. The best course was to explain both the infectivity side and the life-expectation side to both parties, and in most cases that could be done. It was very uncommon to come upon a case of knowing or deliberate infection, and among the educated classes such was practically unknown. Constantly, also, among the patients who came to the London Hospital were men who years before had run the risk of infection, and when contemplating matrimony came to make sure that they were not infected.

Three Groups of Cases.

Dr. H. C. SEMON said that his experience of women at out-patient clinics did not coincide with that which Dr. Routh expressed, for he found that women were more conscientious in their attendances than were the men. He wished to put forward three groups of cases from the point of view of marriage. The first were those having a chancre only, in which the W.R. had not become positive, and no secondaries had developed. If these, after a year of careful observation, preserved their negative W.R., he agreed they might be considered as cured. He had not seen or read of a case which was negative to start with, continued so, and after a year of observation developed a positive W.R. A patient in this group might reasonably be permitted to marry in 18 months. The difficulty was when the syphilis had become generalised (group 2) and was no longer a local disease. These cases must be watched individually; no concrete rule could be laid down until the real meaning of the W.R. was known. Dr. Semon agreed with Dr. Sequeira as to cerebro-spinal syphilis; it was questionable whether a man whose cerebrum had been damaged by syphilis ought ever to be allowed to marry; he could not then be regarded as a normal person, and at any time later he might again develop manifestations in his nervous system. The question of para-syphilitics marrying did not arise; if asked whether a tabetic or a general paralytic should marry, every member of the society would at once give an emphatic negative. In group 3 he would place tertiary cases and those cases still latent after three years of thorough treatment. He agreed that such cases were no longer infectious in the great majority of cases. With the diffusion of knowledge now so general, he should in his own practice (besides continuing treatment of the husband) insist on treating the wife during the first six months of her first pregnancy at least. All statistics concurred in the success that attends rigorous antenatal measures.

A Family Practitioner's Experience.

Dr. HENRY MENZIES, invited by Dr. Fox to give the meeting the benefit of his experience as a family practitioner, said that he had seen certain interesting cases. He remembered four people who had syphilis and afterwards married and had healthy families, and then, in later years, developed definite syphilitic symptoms. One man developed ataxy,

with a positive W.R., in late married life; his wife and children remaining healthy. Another developed ataxy, with a negative W.R.; his family were healthy. One man had syphilis when he was 20, married when he was 25, and had quite healthy children. The man had no illness until he was 70, and then he developed a typical ulceration of the tongue, with mucous plaques. Another man married and had perfectly healthy children, but his wife, after his death, developed cerebral syphilis. He did not think it followed that if a man had syphilis when young, and showed manifestations of the disease later on, that his family were necessarily infected. He would like to know what was the actual merit of the various "neo-" preparations in comparison with the original ones. He had not known the former abolish a positive W.R. in any case, and his view was that the new preparations were but a feeble imitation of the real thing.

Congenital Syphilis in Children.

Dr. D. N. NABARRO said that most people were agreed that the W.R. was a very valuable test of the presence of syphilis; he thought a positive W.R. always meant syphilis, but whether a positive W.R. in a patient who had syphilis many years ago meant present syphilis in an active state was another matter. If a man had had syphilis ten years, he would, as a rule, no longer be infective to his wife or children. His experience of the disease had been obtained largely at the Hospital for Sick Children, Great Ormond-street, and therefore mainly in regard to congenital syphilis. The treatment of congenital syphilis in older children had so far been disappointing. Unless one had the patient very young, it was very difficult to procure a permanent negative W.R., if that was to be aimed at as an indication of cure. He had given 40 to 45 injections to children without favourably altering the W.R. at all in some cases. Nevertheless, their general condition was often much improved by the treatment. If the children could be seen within the first few months of life, then one or two courses of treatment by injections of arsenic and with mercury would render the W.R. negative; in most it would remain so, and the patients would show no sign of disease. Some relapsed, and then another course of treatment again made the W.R. negative. He had had such patients under observation only for six years as yet, and that was not sufficiently long to enable him to say whether they were cured. They must be kept under observation until they were 20 years of age, or longer, before it could be said no further manifestations were likely to occur. It was not yet known whether syphilis was a life-long infection. On that account he was entirely with Dr. Routh in his advocacy of establishing as widely as possible the antenatal treatment of syphilis—namely, the treatment of the pregnant woman. If congenital syphilis could be made a notifiable disease it would help, because it would enable the profession to get into touch with syphilitic families; the mother could then be induced to undergo a course of treatment, as she could be practically promised that it would result in her giving birth to a healthy child. The mother would thus have every incentive for undergoing treatment, for it was she who had all the trouble with syphilitic babies; she had to bring them regularly to the hospital for treatment, and even then a cure could not be promised; moreover, children did not like the treatment. Dr. Routh had said that the husbands ought to be induced to come for treatment; in Dr. Nabarro's experience it was very difficult to get them to come, and often their work prevented their getting there before 6 P.M. He supposed that it must be accepted as true that when a child was syphilitic the mother also had the disease, yet he had a few cases in which the mother's W.R. was negative, even after provocative injections. One case was that of a congenital syphilitic father whose child gave a positive W.R., the mother being negative. This was the only case of the kind he had had. With regard to the question whether a mother

was always syphilitic if she was once infected by her offspring, he had seen families in which the mother had had one, two, or three syphilitic children, yet from later pregnancies the children had been non-syphilitic. He thought the syphilitic virus diminished in intensity and infectivity as years progressed, and that though the mother might have been originally heavily infected and had no treatment, as the years went on she eventually had healthy children.

Dr. MORNA RAWLINS, speaking of women who gave a negative W.R. and had babies who were congenitally syphilitic, said that if one looked on ahead one would probably find that even with a negative W.R. a patient might develop some syphilitic sign or some nerve lesion. Therefore if a woman bore a syphilitic child, even though her W.R. might be negative, she should be treated as a syphilitic patient.

Dr. FOWLER WARD said he had found that if syphilitic children were treated for three years and upwards they did extraordinarily well. Many of the children had not any very definite syphilitic lesion; they had headaches and were ailing in a general way. When put on to intravenous injections they improved out of knowledge. As he was in a small town he knew the patients, and the mothers continued with the treatment for their children five, even to ten, years. With regard to the psychological effect of the injections the great point was to instil confidence. With regard to forbidding syphilitics to marry, in all the 20 years of his practice he had never been asked about the marriage of syphilitics, and from that fact he concluded that syphilologists were barely touching the fringe of the subject. He agreed with Sir James Purves-Stewart that the only way to combat this disease was by education.

Compulsory Notification.

Dr. DENNIS VINRACE accentuated the importance of encouraging patients who had suffered from V.D. to be examined from time to time by practitioners in venereal work. Such a course would spare the feelings of persons who had been infected and guide them as to their conduct and the treatment they required. Male V.D. patients should marry as early as permissible; they would do less harm to the community as married men than as bachelors. A doctor should not betray confidences; he had no right to acquaint a wife of her husband's misdoings, but he could treat the wife sub rosa. Compulsory notification of V.D. would defeat its own ends. It was only required for poor, helpless, and ignorant persons. As regards the educated and upper classes, any such provision would not only convert the doctor into a statutory policeman, and compel him to betray his trust, but deprive him of his legitimate fees. Such persons would employ chemists or quacks or treat themselves. As regards Sir James Purves-Stewart's hope that ultimately a vaccine would be discovered for the prevention of V.D., Dr. Vinrace considered that if it were provided the immorality of the community would be vastly increased.

Dr. H. WANSEY BAYLY expressed his appreciation of Sir James Purves-Stewart's statements concerning the need for the education of the public as the best means of bringing about healthy marriages. He felt convinced that concentrating effort in treating the patient after he had acquired the disease was a very inadequate means of combating the state of things. Everybody, particularly children and adolescents, should be taught that the only way to avoid contagious diseases was to avoid contact; but his experience had been that the adult was not sufficiently impressed by argument alone as to the morality of the matter, but that he was susceptible to appeals to his honour. It should be impressed upon him that it was his duty, as a citizen, if he should acquire the disease, to take such steps as would minimise the possible evil effects on innocent persons with whom he might afterwards be associated.

The Case of the Engaged Man.

Colonel L. W. HARRISON reminded members of Sir Jonathan Hutchinson's teaching, that he knew only

two instances of transmission of the disease to children by men who had followed his requirement of two years of treatment, though many of them had themselves suffered from later manifestations. That seemed to show that the transmissibility died out in time: Colonel Harrison usually advised patients to wait four or five years. In this discussion the case had not been mentioned of the man who found himself to be infected when engaged to be married; if he did not get married fairly soon, there would be a good deal of family trouble. What should be done there? Should everything be broken off because the infection seemed too recent to permit of marriage, or was there a means of preventing infection of his wife if he did marry? The effect of antenatal treatment in preventing transmission was suggestive, and he thought that, so long as a man remained actively under treatment and was reacting normally, he was very unlikely to transmit the disease, even though infection was recent. He suggested this solution of a difficulty which most doctors would admit was sometimes very real. Gennevich had recorded many cases of men who had received his intensive courses of "606" and mercury, and had been allowed to marry within two years of infection, fine healthy families having resulted. He suggested that experience might prove that after intensive treatment, thoroughly carried out, patients could be allowed to marry with safety sooner than had formerly been considered possible.

Reply to the Debate.

Dr. ROUTH said that it seemed, from the discussion, that the profession was not yet quite sure how long, on the modern methods of treatment, a syphilitic subject should be required to be treated before marrying. It almost seemed that modern methods were not so sure as those carried out by Sir Jonathan Hutchinson, but there must be a flaw in this argument. Still, mercurial treatment in 1905 sufficed to procure healthy children, and that needed explaining. It had to be carried out continuously in those days, whereas now it was thought by many that a negative W.R. meant cure, and that there was no necessity for continuing the treatment. With regard to the question whether mothers who had borne syphilitic children were always themselves syphilitic, Dr. Routh suggested that it might be assumed that with each pregnancy the woman was circulating a larger dose of the substance which kept the spirochaetes quiet, so that eventually they were rendered quite inactive and she bore healthy children. He was glad to hear Dr. Nabarro emphasise the importance of treating the syphilitic mother before the birth of the child, in preference to treating, over a long period, the child after birth. He felt strongly that this was the only way to get rid of congenital syphilis.

EXHIBITION OF CASES AND SPECIMENS.

Dr. SEMON described a case of

Tabes with Recurring Herpes Zoster.

The man, aged 35, had well-marked ataxia, absent knee- and ankle-jerks. Both pupils reacted sluggishly to light; there was loss of the stereognostic and orientation senses in the left hand. The patient dated his infection from 1904, and in 1909 he was treated for diplopia. Dr. Semon had been giving him silver salvarsan, and after the third injection the patient showed him a patch of herpes on the front of the right thigh, saying that he had been subject to these recurrent eruptions for the last five years. It always appeared after a bout of pain. Dr. Henry Head had described such cases in Clifford Allbutt's "System of Medicine," stating that it was a very rare phenomenon, and that he had only seen five cases in all. With the injections now being given, the differential diagnosis between an arsenical eruption and one due to tabes became important. In this particular case the eruption had involuted completely, although a subsequent injection had since been given.

Major A. T. FROST spoke on the subject of

Thyroid Deficiency in Subjects of Syphilis.

The cases shown at the November meeting of the Society had all progressed in a satisfactory manner; those which had previously been having frequent relapses had shown no signs since, and about half of them now had a negative W.R. on the ordinary treatment, which had been taken for years before without making any difference to the reaction. Half the cases had changed from a positive to weak-positive W.R. He suggested that much of the reduced vitality in syphilis, especially in the later stages, was due to thyroid deficiency, and that the lethargy and inertia probably were due to infection of the ductless glands, the thyroid among them. One case had relapses two or three times in three years, though all the time he was having fairly intensive courses of treatment. Eventually he showed jaundice, and later erythema as a result of the treatment with arsenic. The speaker then found signs of thyroid inefficiency, and put him on thyroid treatment. Following this, high doses of arsenical compound were renewed, and no sign of arsenic intolerance has occurred. Arsenic alone did not attack the organism of syphilis, and he thought there must be a substance in the blood increased or stimulated by the ductless glands secretions, which, uniting with the arsenic, operated efficiently on the disease without organotropic effects from the metal, if this substance is in sufficient quantity. He commended the suggestion for study by the Society.—Dr. FOX said that the matter should be followed up. A series of cases should be treated with thyroid at the same time, so that statistics could be compiled.—Dr. FOWLER WARD said a man with tertiary ulceration of the shin had not made any progress on the ordinary N.A.B. treatment, but since he had been having thyroid (as suggested at a former meeting), though the W.R. had not become negative, healing had been quite rapid.—Dr. SEQUEIRA asked if any member had had experience in the treatment of syphilis in myxomatous patients.—Dr. NABARRO said he had had cases of children who had had as many as 40 injections and yet retained positive W.R. throughout. Since, at the last meeting, it was suggested that these stubborn cases might be due to some of the glands not acting properly, some patients were tried on thyroid, some on parathyroid, some on mixed-gland extract, and there had been encouraging results. One case which had a positive W.R. for 14 years had now become negative. In addition, one or two of the children were now mentally brighter.—Dr. H. M. HANSHELL said that at the meeting in November he was much interested in this subject, and at that time he had in hospital a lascar who had had a relapse, and mercurial and neokharsivan treatment had no apparent effect on him. He could not find that the man lacked thyroid secretion; he was hairy, and in every way fit. He had a persistent rash and an unhealed chancre. He was given thyroid and the whole condition cleared up.

Gumma of Tongue.—Gumma of Right Calf.

Dr. VINRACE showed a case of gumma of tongue of four months' duration in a man aged 50. He was a platelayer and had contracted syphilis at the age of 29. It was treated for the following two and a quarter years and apparently cured. No more treatment nor symptoms occurred till November, 1922. In February, 1923, he attended St. Paul's Hospital with ulcer of tip and adjoining edge of the tongue. W.R.++. At the age of 38 he had become the fourth husband of a widow then aged 40. She died of G.P.I. ten years after the marriage; there was no pregnancy; history of the three previous husbands was not available. An alternative diagnosis of epithelioma and biopsy was suggested by Dr. Sequeira.

Dr. VINRACE also showed a case of gumma of the right calf of six months' duration in a man aged 51. He had been married for 30 years, contracted syphilis eight years ago, and had had no coitus since then. He was treated for a few months following infection and then had no treatment for some years. In April,

1922, he attended St. Paul's Hospital for three weeks with numerous tertiary ulcers of six or eight weeks' duration. In March, 1923, he attended St. Paul's Hospital again. Numerous cicatrices on right arm and forearm, on the lower thigh, and upper knee and ankle, and a large deep gummatous ulcer on the right calf.

Cases.

Dr. FOX showed a case of double infection and one of primary sore inside the lip.

ROYAL MEDICO-CHIRURGICAL SOCIETY OF GLASGOW

A MEETING of this Society was held on April 6th, Dr. T. MORRIS CRAWFORD, the Vice-President, in the chair, when a discussion took place on the

Diagnosis of Pulmonary Tuberculosis, with Special Reference to Radiology.

Dr. LEONARD FINDLAY referred particularly to the malady in the young, and stated that his conclusions were based upon clinical, radiological, and pathological examination of the material, and that meticulous care had been taken in the matter of diagnosis. Dr. Findlay's belief was that in the ante-puberty period of life tuberculosis of the lungs is a disease of infancy and early childhood, and that it runs an acute or subacute course. In an older child a pulmonary lesion, and especially a chronic pulmonary lesion, should be diagnosed as of a tuberculous nature only with the greatest hesitation and in the presence of the utmost proof. Charts were shown in support of this thesis. Dr. Findlay also pointed out that pulmonary tuberculosis, unless in the very young infant, is seldom, if ever, limited to one lung or one lobe of the lung.

Dr. D. CAMPBELL SUTTIE explained how difficulties arose with regard to the interpretation of X ray films, and showed films of cases of pulmonary tuberculosis. Dr. Suttie's conclusions were: 1. Admittedly recognisable X ray appearances have a definite value in the face of negative clinical findings. 2. Negative X ray appearances have no claim for consideration when clinical signs are undoubtedly present. 3. There are pathological conditions which in their early stage are undetectable by either—e.g., miliary tuberculosis. 4. Certain pathological conditions are shown by radiograms (a) before clinical signs or symptoms appear and (b) after clinical signs or symptoms have disappeared. 5. Certain pathological conditions are detected by the clinician before X ray appearances are present.

Dr. A. S. MACGREGOR introduced the subject from the point of view of the Department of Public Health, and referred to the work done by Dr. J. A. Wilson and Dr. F. L. Henderson and himself in correlating clinical and radiological features in special groups of cases. Some of the earlier ideas as to the nature and apparent abnormalities in X ray films had had to be discarded, and radiographic appearances varied within wide limits in normal chests. From the point of view of routine diagnosis of lung conditions, perhaps the most important aspect of radiology was the aid it gave in a negative sense in doubtful cases. In this respect the right apex was a constant stumbling block. It was also of value in many cases of chronic bronchitis where the symptoms suggested a coexistent tuberculosis. Reference was also made to the hidden, unsuspected, and otherwise undiagnosable lesions which X rays often detect.

Dr. J. A. WILSON, who followed, stated that if one analysed the cases notified as pulmonary tuberculosis in a district of Glasgow, it would be found that the error in diagnosis, in the best year, was about 33 per cent. For the past three years efforts had been made to evolve a scheme to deal with the increasing number of notifications of cases which were doubtfully tuberculous. While it was perhaps too early to dogmatise, the conclusions come to as a result of the combination of careful X ray and clinical work were: 1. Cases of tuberculosis of the lung have a definite radiological

picture. 2. Hilus tuberculosis is an uncommon disease. 3. Basal lesions are, as a rule, non-tuberculous, the exceptions being those secondary to a chronic tuberculous infection of the abdomen. 4. There may be physical signs of moderately extensive infection of the respiratory tract with no radiological counterpart. These infections are non-tuberculous.

Dr. FERGUS L. HENDERSON gave a demonstration of X ray films and slides illustrating points in radiological diagnosis of tuberculous disease of the lung.

Reviews and Notices of Books.

TROPICAL MEDICINE.

The Practice of Medicine in the Tropics. Vol. III. By many authorities. Edited by W. BYAM and R. G. ARCHIBALD. Oxford Medical Publications. London: Henry Frowde and Hodder and Stoughton. 1923. Pp. 960. £4 4s.

THE third and final volume of this exhaustive work has now appeared, some three years after the first of the series was reviewed in THE LANCET. The subject-matter is diverse: it includes sections on helminthiasis, heat-stroke, disorders of metabolism (deficiency diseases), and diseases of doubtful causation. The section on regional diseases embraces diarrhoeas in the tropics, ophthalmology, and the heart in chronic tropical diseases. The last three sections are devoted to skin diseases, diseases of women, and surgery respectively. The eagerly expected section on helminthiasis is mainly from the pen of Clayton Lane, in parts in conjunction with G. C. Low. It will doubtless be scanned by many a critical eye, for an authoritative account of medical helminthology has long been wanting. Special attention has been paid to the nomenclature, with the result that *Dibothriocephalus latus* has become *Diphyllbothrium latum*, and the familiar *Oxyurus* converted to *Enterobius vermicularis*. It is doubtful whether the original drawings which illustrate this section will convey to the student all that he wishes to learn; to the unzoological eye sagittal sections of trematodes are apt to be misleading. An entirely satisfactory account of human helminthology, written from a medical standpoint, has always presented many difficulties, and this is an advance on any yet extant.

Schistosomiasis is treated in a lengthy article of 76 pages, which is the combined work of six collaborators—N. H. Fairley, A. R. Ferguson, H. S. Houghton, F. C. Madden, P. H. Manson-Bahr, and I. F. G. Martinez. The subject is fully illustrated with beautifully coloured plates, maps, and diagrams. Hydatid disease is discussed from a clinical standpoint by L. E. Barnett, and the surgery of this dangerous condition is fully dealt with. The chapter on ankylostomiasis is from the pen of Bailey K. Ashford. The section on filariasis, by J. W. W. Stephens and Warrington Yorke, contains a summary of the views of authorities on this subject, and the description has in places become controversial. Infection with *Loa loa* (designated *Loiasis*), *Acanthocheilonema perstans* (*Acanthocheilonemiasis*), and *Onchocerca volvulus* are also considered. Disorders of metabolism commences with a useful chapter, by E. E. Waters, on diabetes in the tropics, a subject not usually considered in books on tropical medicine. Deficiency disease, scurvy, beri-beri, epidemic dropsy, and the whole subject of vitamins is dealt with by E. B. Vedder in one of the best chapters in the book. Pellagra, beautifully illustrated, is treated by G. M. Miles. J. A. Arkwright and Sir William Willcox are responsible for the account of typhus fever, and this section, as well as that on Rocky Mountain spotted fever, by B. S. Wolbach, is excellent. An account of trench fever is given by the senior editor, W. Byam, who has already written much on this disease, while we are grateful for an authoritative and modern description of tsutsugamushi disease to the Japanese investigator Mataro Nagayo. Oroya fever and verruga

peruviana are considered together in an article based upon the original work of R. P. Strong. The section on dengue is by J. B. Cleland, while L. P. Phillips, of Cairo, deals with phlebotomus fever. Rabies is presented by W. F. Harvey and A. G. McKendrick; an excellent description of small-pox, by S. Sabongy Bey, is adorned by many telling photographs. Sprue is discussed by P. H. Manson-Bahr, diarrhoeas in the tropics by J. Cunningham, and ophthalmology by R. H. Elliot. R. M. Wilson contributes a chapter on the heart in chronic tropical disease. The section on skin diseases, by A. Castellani and A. J. Chalmers, is mainly remarkable for the beautiful plates by Terzi; scabies is considered in a separate chapter by J. W. Munro. Diseases of Women in the Tropics is by Grace Mackinnon, and will be found full of useful information to the tropical practitioner, who is also well served by the profusely illustrated account of surgery of the tropics, entrusted to F. C. Madden.

The editors may be complimented on having concluded their task in so satisfactory a manner, and on having produced a monumental work which is a credit not only to the science of tropical medicine but also to the practitioner in the tropics.

Laboratory Studies in Tropical Medicine. Fifth edition. By C. W. DANIELS, F.R.C.P., Consulting Physician to the Hospital for Tropical Diseases, and H. B. NEWHAM, C.M.G., M.R.C.P., Director of the Department of Tropical Pathology and Warden of Studies, London School of Tropical Medicine. London: John Bale, Sons and Danielsson, Ltd. 1923. Pp. 576. 25s.

IN hardly any department of medicine is laboratory technique so essential as in the study of tropical disease; a new edition of a book already familiar to generations of students will, therefore, be welcomed. If regarded as an introduction to the subject, and not as an exhaustive presentation, it will be found adequate to its purpose, for laboratory technique is set forth in simple language and in instructive style. The general arrangement of the book in previous editions is maintained, while recent advances in intestinal protozoology and in helminthology receive attention and have necessitated the inclusion of additional illustrations. One adverse comment may be made with reference to the description of the Wassermann reaction. In a laboratory text-book a detailed and intelligible description of a rather elaborate technique might be expected. The method here advocated has not received universal approbation, and a more generally accepted method, such as the one adopted by the Medical Research Council, should have been substituted. The brief introduction to entomology which completes the volume is admirably adapted for the student.

THE TREATMENT OF FRACTURES.

With Notes about a Few Common Dislocations. Ninth edition, revised. By CHARLES LOCKE SCUDDER, M.D., Consulting Surgeon to the Massachusetts General Hospital. London and Philadelphia: W. B. Saunders Company, Ltd. 1923. With 1252 illustrations. Pp. 800. 42s.

AMERICAN surgery has provided us with at least three outstanding monographs dealing with fractures, not the least distinguished of these being Scudder's work which has been repeatedly revised since its first appearance in 1900. At the Massachusetts General Hospital, Boston, where Dr. Scudder himself laid the foundations of the special fracture service which functions to-day, the rising tide of abdominal surgery of the past 20 years has never engulfed this more prosaic but equally important department of surgery.

In the present edition there is the same profusion of useful illustrations and descriptions of varied methods which characterised previous issues of the book. Dr. Scudder has been more than generous to many surgeons in the full reference he has made to the technical advances of the past decade. The question remains whether it is worth while to continue to reproduce the

minutiae of so many different methods of handling and splinting limb fractures. Recent warfare experience has taught us how essential it is that there should be the utmost simplicity both in the enunciation of principles and in the application of the same. For example, in the section dealing with fractures of the femur, we fail to discover Dr. Scudder's own views based on the maturity of his experience. No doubt there are many different ways of obtaining a passably fair result in any given fracture. Many of the popular and conventional methods, however, are known to be technically unsound. Thus we regret to see in this important work the inclusion on a large scale of illustrations depicting the application of flat wooden splints.

Dr. Scudder's book will lose none of its well-deserved popularity, and the influence of the author in the direction of stimulating a better organisation of fracture treatment in hospitals will continue to be felt far and wide.

THE BACTERIOPHAGE.

Its Rôle in Immunity. By F. D'HERELLE, Pasteur Institute. Authorised translation by GEORGE H. SMITH, Ph.D., Assistant Professor of Bacteriology and Pathology, Yale University Medical School. Baltimore: Williams and Wilkins. 1922. Pp. 287. \$4.50.

THIS is an American translation of d'Herelle's well-known monograph, and it is a welcome addition to bacteriological literature, since it sets forth for the first time in the English language the views and work of the author upon the remarkable phenomena now associated with his name. We have already reviewed the original, and the translation differs from it but little, except that Chapter IV., which deals with the essential nature of the agent of the phenomenon, is new. This practically sets forth the arguments advanced by the author at the British Medical Association's meeting last year, and he maintains in the face of all criticism the essential living nature of his bacteriophage. A full bibliography is given and this has been brought up to date. We note the omission of Twort's name, although his work is referred to in the text. The translation has been well carried out, but we must protest against the rendering of "Je l'ignore" as "That must be ignored."

DISEASES OF THE EAR, NOSE, AND THROAT.

Medical and Surgical. Sixth edition. By WENDELL CHRISTOPHER PHILLIPS, M.D., Professor of Otolaryngology, New York Post-Graduate Medical School. Philadelphia: F. A. Davis Company. 1922. Pp. 881. \$8.

THIS work is a well-known standard text-book in the United States. The first part, on diseases of the ear, forms nearly one half of the entire volume; it is well written, beautifully illustrated, and full of helpful detail in just those difficult minutiae for which the practitioner will wish to seek its advice. We have not read anywhere a more lucid description of the intricate subject of testing the function of the vestibular apparatus. Immediate closure of the wound after antrotomy is described under the so-called "blood-clot" method of after-treatment; the author says that "unfortunately the results have not seemed to warrant its general employment," but he makes no mention of immediate suture after sterilising the cavity with alcohol and bipp, a method which has given excellent results in this country. He recommends the practice, in thrombosis of the lateral sinus, of removing the clot located in the jugular bulb with a curette before ligation of the jugular vein, a manipulation which would appear to be highly dangerous. Apart from a few such points, we have nothing but praise for this section of the book. The remaining part is divided into a section on general diseases, including tuberculosis and syphilis, and a final section on diseases of the nose and sinuses, pharynx and fauces, and the larynx. By comparison with the section on the ear, the

remainder, especially the part on the larynx, is somewhat disappointing; it lacks the sure touch and fullness of practical detail marking the former part.

Important subjects are dismissed too quickly for a book of this size; for instance, only five lines are devoted to the surgical treatment of naso-pharyngeal fibromata. The chapter on the diagnosis and treatment of cancer of the larynx is particularly disappointing; of operative methods the author recommends complete laryngectomy for practically all operable cases, and states that laryngo-fissure "can rarely be employed because it is applicable only to cases where the disease is limited to an extremely small area." He mentions a case where the entire diseased area covered less than one-half of the vocal cord; nevertheless, a hemi-laryngectomy was performed, and the patient survived for 14 years. In this country the operation selected would have been laryngo-fissure, the prospect of recovery would have been as good, and the mutilation much less. Dr. Phillips has entirely neglected the brilliant work done in England by Butlin and Semon and their successors. In fact, throughout the book very little reference is made to workers outside America, a fact which, however, is made the subject of a prefatory warning.

PEDIATRICS.

Edited by Prof. E. FEER, Director of the University Children's Clinic, Zurich. Translated and edited by JULIUS PARKER SEDGWICK, B.S., M.D., Professor of Pediatrics, University of Minnesota Medical School; and CARL AHRENDT SCHERER, M.D., F.A.C.P. London and Philadelphia: J. B. Lippincott Company. 1922. Pp. 917. 42s.

THIS large volume should be valuable to those to whom the original German edition is not available. Such well-known writers as Finkelstein, von Pirquet, and Noeggerath are responsible for various sections, which have been translated and edited by American physicians. We regret that the German phrases, even though ponderous, have been rendered in colloquial English, if not actually slang, unsuitable to a text-book. For the rest, though we may hope that the student will still prefer the succinct clinical pictures of the great British teachers, whoever turns to this volume cannot fail to find a mass of valuable knowledge and a very thorough survey of the subject.

ORGANIC CHEMISTRY.

A Method for the Identification of Pure Organic Compounds by a Systematic Analytical Procedure Based on Physical Properties and Chemical Reactions. Vol. IV. By Dr. S. P. MULLIKEN, Associate Professor of Organic Chemical Research at the Massachusetts Institute of Technology. London: Chapman and Hall. 1923. Pp. 238. 30s.

THE fourth volume of this work constitutes a comprehensive record of an arrangement of organic compounds whereby their identification is facilitated. With the publication of this volume the most important portions of the special analytical field with which the "Method" is concerned are so far covered that the chemist who is engaged in the identification of any well characterised, pure organic compound may turn to its tables with at least a reasonable hope of assistance in the solution of his problem, provided the compound has been previously described and possesses some apparent general interest. Volume IV. adds to the "Methods" 14 "orders" or groups of compounds containing new combinations of elementary atoms, and about 3900 additional specific characterisations to the previously completed descriptions. The selection of compounds is the result of a scrutiny of the entire list of compounds mentioned in the last completed edition of Beilstein's "Handbuch" and of the first three volumes of the edition now in progress of publication, and also includes

many other species of evident interest described in the more recent periodical literature.

The greatest care must have been exercised in the compilation of this monumental work, and organic chemists are indebted in no small degree to the author and his associates.

Richter's Organic Chemistry. Vol. III.: Heterocyclic Compounds. Translated from the eleventh German edition by G. E. F. D'ALBE, D.Sc. London: Kegan Paul, Trench, Trübner and Co. 1923. Pp. 326. 25s.

THIS third volume completes the translation of the eleventh German edition of the well-known Richter's Organic Chemistry as edited by Anschütz and Meerwein. It deals in a systematic manner with 3, 4, 5, and 6 membered heterocyclic compounds. The vegetable alkaloids of the pyridine, tropine, cinchonine, morphine, and isoquinoline groups are treated in a fairly comprehensive manner from the structural point of view. It is to be regretted that in most of the references to the published literature the number of the volume only and not the year is given. This lapse in a standard work is to be deplored.

NURSING OF DISEASES OF THE EYE.

A Simple Treatise for Nurses. By JESSIE ELMS, A.R.R.C., Matron, Sussex Eye Hospital, Brighton. London: The Scientific Press, Ltd. 1923. Pp. 70. 2s. 6d.

OF the 70 pages in this book only 13 are devoted to the subject of practical nursing, the rest being an elementary account of the anatomy of the eye, and a list of instruments used in eye operations. Nurses are creditably hungry for knowledge, but we fear that many of them will rise from the perusal of this manual with an unsatisfied appetite. The chapter on methods of treatment is good, so far as it goes, but would be much better if more information were given on the dangers of some of the drugs in common use, and the best methods of avoiding these—we refer more especially to atropine irritation and the roughening of the cornea which follows the careless use of cocaine. The hints about food in the days succeeding an operation for cataract might well be supplemented by details of the food actually given in an eye hospital. As to theatre work, an ophthalmological surgeon would not care to operate with the sole assistance of a nurse whose teaching on the subject was confined to that enunciated in this little book.

THE URETHRA AND THE URETHROSCOPE.

By F. CARMINOW DOBLE, M.R.C.S., L.R.C.P. Oxford Medical Publications. London: Henry Frowde and Hodder and Stoughton. 1923. Pp. 120. 10s. 6d.

THE increase in venereal disease associated with the war has brought with it a flood of new books on the subject of its diagnosis and treatment, and during the last three years a great many reviews of new text-books on venereal subjects have appeared in these pages. With the exception, however, of Luys's "Cystoscopy and Urethroscopy" and a small manual by Dr. Norman Lumb, few books written in the English tongue have devoted themselves to the subject of urethroscopy. This little volume by Dr. Doble deals entirely with urethroscopic methods of diagnosis and treatment. Lesions of the urethra and their pathology are only described in so far as they have a bearing on urethroscopy, and the only methods of treating chronic gonorrhœa given are those which are applied through a urethroscope. The first portion of the book is devoted to descriptions of different models of anterior urethroscopes, all of these, with the exception of Luys's and Vallentine's, instruments being of British design and manufacture. Amongst urethroscopes for the posterior urethra the author includes descriptions of the Wossidlo-Goldschmidt, Luys, Wyndham

Powell, and Swift Joly instruments. In addition to these is a special adjustment designed by himself which may be fitted to the anterior urethroscope, manufactured by the Holborn Surgical Instrument Company. This consists of a long, straight tube, an elbowed obturator to facilitate its introduction into the posterior urethra, and a longer lamp bracket so that the illumination may be brought to the end of the examining tube. Dr. Doble apparently does not consider that water distension is an essential to satisfactory vision in the posterior urethra, and here there will be many who will join issue with him. The descriptions of the different instruments are clear and precise. The work, moreover, has been well illustrated and contains, in addition to drawings of instruments, coloured plates showing the commoner lesions of the anterior and posterior urethra. It is certainly the best guide to urethroscopy that has appeared from the pen of an English writer, and its general get-up and finish are excellent.

JOURNALS.

QUARTERLY JOURNAL OF EXPERIMENTAL PHYSIOLOGY. Edited by E. SHARPEY SCHAFFER and others. Vol. XIII. No. 1. Pp. 1-103. London: Charles Griffin and Co., Ltd. 10s.—The Action of Extracts of Endocrine Glands upon Motor Nerve and Skeletal Muscle, by Misao Yoshimoto. Extracts of the pituitary body—anterior and posterior lobe—pineal gland, brain matter, thyroid, parathyroid, thymus, suprarenal, testicle, ovary, and also choline hydrochloride, histamine acid phosphate, tyramine acid phosphate were applied to the isolated nerve and to the sartorius muscle of the frog. The results show that there is but little reason to suspect any specific physiological effect of the endocrine glands on motor nerve or striated muscle. The restoration of nerve function in Ringer's fluid after being affected by these substances is generally complete, while that of muscle is not uniformly so.—The same author describes the Action of the Blood Serum of Animals in Tetania Parathyreopriva on Motor Nerve and Skeletal Muscle. The frog's sciatic nerve and sartorius were used. The serum of thyreo-parathyroidectomised dogs and cats produces some increase of excitability in the isolated nerve of the frog, but has no special effect on the contraction of isolated muscle. The serum of both thyroidectomised and normal dogs and cats has practically no effect on frog's nerve. A solution of guanidine carbonate causes some increase of nervous excitability. Taken in conjunction with the results of other workers on tetany, the author concludes that the serum of animals in a condition of tetania parathyreopriva may contain some exciting substance which is present in just sufficient amount to affect the excitability of motor nerves, but not of muscles. Some guanidine-like body may be the agent in producing the hyper-excitability of peripheral motor nerves in tetany.—Effects of Lowering the Temperature in Homiothermic Animals, by S. W. Britton.¹—A Method for Recording Gastric Secretion in Acute Experiments on Normal Animals, by Robert K. S. Lim. The most suitable animals are cats and dogs, especially cats, and the experiment is best performed on chloroformed animals at or shortly after the time of the usual morning meal, a procedure which ensures that the stomach is empty and that the glands are in a normal state of repletion. A perforated glass cannula is introduced into the stomach through the pylorus to drain the stomach of its juice, which is allowed to activate a drop-recorder after its escape from the organ. A balloon is also inserted into the stomach to serve as a control of motor changes. The method permits of observation being made on the latent period, and the duration and quantity of the secretion after the introduction of a suitable excitant. The juice thus obtained invariably contains free HCl and pepsin.—The Question of Gastric Hormone, by

Robert K. S. Lim. Using the method just described, extracts of the fresh organs employed were administered through the external jugular vein of cats. The author confirms the observations of Eddins regarding pyloric extracts and their effects in causing gastric secretion. Extracts made from the cardiac and duodenal mucous membranes are less active; fundus extracts are comparatively inert, while jejunal and ileal extracts are ineffective. Histamine causes gastric secretion when injected intravenously. Adrenalin does not inhibit the secretion provoked by the substances named, but may delay outflow from the stomach. Adrenalin excites secretion in some individuals. The distribution of the gastric excitant or gastrin in the stomach and duodenum corresponds with the distribution of mucoid glands; it is suggested that the excitant is extracted from mucoid cells. The blood of fed animals has no effect on gastric secretion when transfused directly or indirectly. Since there is no exciting substance in the blood after meals, it is concluded that the excitant found in the pyloric and other extracts is not secreted into the blood-stream, and the mechanism of secretagogue action is not due to internal secretion.—Does the Depressor Nerve Contain Efferent Fibres? E. Sharpey Schaffer and M. L. Walker find that the depressor contains no efferent fibres, but is purely afferent.

ARCHIVES OF INTERNAL MEDICINE. March, 1923.—J. H. Means and G. W. Holmes (Boston) report two series of cases showing the effect of Rontgen ray treatment of toxic goitre. Cases of toxic adenoma and exophthalmic goitre are dealt with and evidence is produced of the beneficial effect of X ray therapy. The report is one of a series emanating from a thyroid clinic in which there is close co-operation between internist, surgeon, and radiologist.—L. Kessel, C. C. Lieb, and H. T. Hyman (New York) describe the clinical course of exophthalmic goitre based on the observation of 50 fully developed cases. A uniform plan of treatment was adopted; it consisted of rest, high caloric diet, the best obtainable hygienic and psychic conditions, and the administration of syrup of ferrous iodide. A marked tendency to recovery, sometimes interrupted by relapses, was observed.—W. J. Kerr and G. C. Hensel record observations on the cardiovascular system in thyroid disease, with special reference to the types of irregularity revealed by means of electro-cardiograms and polygraph tracings. Of the 181 goitres studied, 123 are classified as adenomas and 58 as hyperplasias. Auricular fibrillation or flutter was present in about one-third of all toxic cases. Prognosis and treatment are discussed.—L. E. Viko, H. M. Marvin, and P. D. White (Boston) contribute a clinical report on the use of quinidine sulphate. They show that the response to quinidine is better in recent cases and in those without circulatory congestion, and it is less likely to be permanent in those with ectopic beats. Sex, age, valvular disease, and, in regard to the nature of the disease, arterio-sclerosis compared with rheumatism, are not factors which determine the response to quinidine.—N. C. Gilbert (Chicago) shows the increase of certain vagal effects with increased age.—E. P. Carter and H. J. Stewart: Studies of the Blood Gases in a case of Paroxysmal Tachycardia. Marked decrease of the oxygen saturation and extremely low carbon-dioxide content of the arterial blood and low oxygen saturation of the venous blood were found.—W. L. Rogers (San Francisco) contributes a note on the correlation of vital capacity with stem height.—A case with enlargement of hæmal nodes is reported by M. Lederer (Brooklyn).—A case of rheumatic fever with cerebral symptoms simulating encephalitis lethargica is reported by L. F. Frissell (New York).—W. J. Fetter (Pittsburg) describes a gravimetric method of estimation of phosphates in the blood, and discusses their retention in nephritis.—M. Bodansky and M. D. Levy (Galveston) discuss some factors influencing the detoxification of cyanides in health and disease.

¹ We comment on this paper in our annotation columns.

THE LANCET.

LONDON: SATURDAY, APRIL 21, 1923.

CONTRACT MEDICAL PRACTICE.

INCREASED remuneration is the only point in favour of the panel system. This is the conclusion reached by an experienced practitioner in a rural area, whose interesting letter we print on p. 819. He is comparing the present medical service under the Insurance Acts with the old club system, more especially that of the friendly societies before the year 1911, and his letter deserves careful thought at this juncture. It is an able, sympathetic, and humane statement from one with understanding. We would suggest, however, that the advantage of the capitation basis of payment lies not so much in the amount of the remuneration as in the manner in which it is paid. When the medical benefit clauses of the first National Health Insurance Act came into operation the doctors in each insurance area were asked to choose the method by which they were to be paid. The great majority chose the capitation system, only a few areas adopted payment per attendance, and all of these, after the experience of one quarter, gave it up in favour of capitation with a single exception—namely, the Manchester and Salford area. In the light of the experience now gained, the virtues of the capitation system can be set out thus. The system fixes the responsibility of the practitioner for certain insured persons on his list. The practitioner takes the risk for providing medical treatment for those of his insured persons when they fall ill. The amount of illness varies with the character of the industrial population in the neighbourhood, with the housing conditions and other economic factors due to fluctuations in trade. The risk is correspondingly greater if these conditions are bad, and it is to the doctor's interest to help in improving the environment and conditions of life of the industrial population in his midst. To the insured persons who are ill he can give unrestricted attention, concentrating on the medical aspect of the case without any anxiety as to the financial position of the patient, or any fear of an unpaid bill. He can within the range of human possibility and endurance give them his very best. In regard to those who are not ill but who consult him for trivial or incipient illness, he can interest himself in their personal hygiene, in the nature of their employment, and in their mode of living, and so do real preventive public health work. The commercial side of his practice comes less and less into evidence and the professional side gains more and more in importance. The fixed remuneration enables the practitioner to live in comfort and gives him a wholesome sense of security.

The dangers of the capitation system are those of any system of insurance payment. It provides the scope and, in certain cases, the incentive for the practitioner to neglect his work. It encourages him to get through the necessary work hurriedly and perfunctorily and teaches him to avoid all unnecessary work. This is true of the unprincipled man who is shirking his responsibilities and from whom nothing but shoddy results could be secured by any method of

payment. It is also true of the victim of circumstances who lives in a neighbourhood understaffed with doctors, and who has to accept greater responsibilities than he can cope with either mentally or physically. But the same will hold true by the payment per attendance system under similar conditions. The one advantage claimed for the Manchester system is that it would secure adequate medical attention and make neglect impossible; but it cannot and does not prevent the unprincipled man from multiplying his attendances and visits and reducing each attendance to the most perfunctory service given in the minimum of time. The grave disadvantage of such a system is that the practitioner is not so concerned to keep his patients well; he is deprived in some measure of his interest in the health of the community. To abolish the capitation system would be to exclude the practitioner from the field of preventive medicine.

In contrasting the panel system with the club practice of olden days our correspondent writes: "We dealt with brothers then, we deal with material now." But is the change in the doctor or in his patients? True the old club members were thrifty and provident, while the insured person may be the unwilling contributor to a scheme which he appreciates only in so far as it gives him something tangible in return. Thus he is out to get all he can and to get it in the most material way. He has no sense of assisting in any great scheme to help his invalid comrade. In truth, he has no brother, because he has lost all sense of brotherhood. These people may make themselves seen and heard; there is no evidence that they constitute the majority of insured persons. On the professional side men without any real concern for the public weal and with a poor sense of their own obligations are to be found. They were in the medical profession before the Insurance Acts were passed, but the panel system has brought them into the light. By education and by discipline we may hope to temper these inimical factors. Much may be expected from the new generation of medical men and women, trained in social welfare. The panel system has weathered the storms of a great war and is now contending with the equally severe trials of an unsettled peace. It has great and undeveloped possibilities as an instrument of public health. Private practice will not and should not be superseded by it; there will always be abundant scope for individual practitioners, but the urgent need of the moment is for an army of practitioners of preventive medicine; this the panel system provides, and provides also, if its potentialities are properly recognised, for inter-professional coöperation in every direction. This country is now too urbanised to make possible any return to the actual conditions which RUSTICUS has recalled to memory, with their charms and their drawbacks. But there is nothing to prevent a return to the spirit which infused these conditions in the countryside, save a vague but prevalent distrust. And for the growth of this, unfortunately, the immediate future will furnish a fruitful soil. The approaching responsibility on the Ministry of Health is a very serious one.

DRUG RESEARCH IN INDIA.

INDIA has played a large part in research and discovery in the field of tropical medicine. LEISHMAN, ROGERS, ACTON have left indelible marks on medical history. An organised attempt is now being made to perfect the Calcutta School of Tropical Medicine.¹

¹ THE LANCET, April 7th, p. 728.

One branch of the work suitable for the school was advocated by CHOPRA and GHOSH in a recent lecture before the Medical Section of the Asiatic Society of Bengal—namely, research in Indian indigenous drugs. The work which ACTON, working in India, has done on cinchona may be extended to Indian drugs. To the layman estimating the value of the medical profession nothing is more astonishing than the fact that the doctor does not know if many of his drugs act or not; further, this ignorance does not apply only to harmless but also to potent ones: belladonna, which for years has been given to suppress lactation, is now said to have no action on a gland which has hormone and not a nerve activity; morphine, which is given in suppository form after rectal operations, is now known to have no local action. While much exact experiment has been done on synthetic drugs, less has been done on galenical preparations. The work is laborious, the results are small. We have only to look at the excellently illustrated medical botanies of a hundred years ago to realise how nearly all our plants have been used medicinally; any one of these botanies will, in fact, form a good modern guide to the flowers of the field.

India, too, has used and is using many of its plants for medicinal purposes, but there is more hearsay and less experiment in its choice than in Western countries. In the lecture referred to suggestions are made as to lines which research may follow. First, there are new drugs to be discovered and new uses to be applied to old ones. It is interesting speculation to consider, if all our useful drugs—opium, belladonna, cinchona, caffeine—were suddenly forgotten, whether they would be rediscovered, and how soon. Probably there are others just as potent which have never come to light, and possibly they are without drawbacks which our present drugs possess. Others may have actions more potent than those for which we now use them; digitalis was long used for certain forms of epilepsy before it was reintroduced for dropsy, and it was by exact clinical work it was found to be effective in cardiac dropsy. In all the rich foliage of India, in all the herbs used by the wise men of India, some new preparations are to be found as soon as scientific search is made. Secondly, money can be saved by substituting drugs found at home for better-known imported ones; this is a matter of moment in a country with many of its inhabitants so poor that they cannot afford to buy common drugs such as quinine, castor oil, and magnesium salts. The powdered flowers of a variety of *Artemisia maritima* which grows in the Himalayas is said to form an excellent substitute for the expensive santonin; this is the active principle of the Levant wormseed, a variety of plant which grows in the wildest parts of the Russian steppes and which has so far been the only one known to produce the active principle. Several of the medicinally active species of strophanthus are indigenous to tropical India, and many indigenous members of the Ipomœa family contain jalapin and convolvulin.

The action of drugs can be tested scientifically and exactly only when active principles have been extracted, but when once this exact knowledge has been attained the use of crude drugs is the keynote of cheapness; the use of cinchona febrifuge, a crude drug preparation, works, as shown by ACTON, both for efficiency and economy as compared with quinine. But the scientific examination of drugs is a laborious process in which the chemist plays as important a part as the medical man. It would be well, then, for research to be started on plants to which folk-lore ascribes healing power in definite diseases. No better example of this can be given than the discovery and application of

ethyl ester of hydnocarpic acid, the active principle of chaulmoogra oil, which has put the treatment of leprosy onto a sound basis. Indian pharmacology has a great future, and the Indian student should welcome the responsibility of the accompanying researches.

PRESERVATIVES IN FOOD.

THE use of chemical preservatives and colouring matters in food has long attracted the attention of public health authorities. In the year 1899 a Departmental Committee was appointed to inquire into the whole subject, and after more than 4000 samples of foodstuffs had been analysed at the Government laboratory a report was issued in 1901. It then appeared customary to add preservatives to a large number of food commodities: Salicylic acid or formalin in the case of cream; boric acid in the case of butter, margarine, bacon, and preserved meats; boric acid, salicylic acid, or sulphites in the case of jams, lemon juice, and non-alcoholic drinks. Cheese, condensed milk, lard, preserved fish and vegetables, sugars, and spices were found to be free from preservatives. The amount of preservative ranged widely: Boric acid in meats from 15 to 66 gr. per pound, salicylic acid in drinks from 1.5 to 19 gr. per pint. While this much was ascertained, there was a feeling among experts at the time that the total extent of the practice was not revealed to the Committee, inasmuch as many commodities were not sampled by the officers of local authorities. The Departmental Committee made certain definite recommendations—namely, the absolute prohibition of formalin in any form and of all preservatives in milk, and the restriction of salicylic acid and boric acid within prescribed limits. They were of opinion that salicylic acid when added should be declared to the purchaser, and that no preservative whatever should be added to foods intended for invalids or infants. The report was circulated and attracted wide attention but, in the easy fashion of the time, was not embodied in legislation. The only official action taken on the recommendations was the issue of the Cream Regulations (1912 and 1917) limiting the amount of boric acid or hydrogen peroxide which might be added to cream, and making obligatory an announcement on the label.

And so the position has remained until now. Two London medical officers of health have recently advised their public health committees that something more should be done. Dr. C. W. HURT (Holborn) points out that in the 20 years or more which have elapsed since the Departmental Committee reported considerable scientific progress has been made, and that it would be reasonable now to enforce a declaration of the presence and amount of any preservatives added to food and to set up definite maxima which must not be exceeded. The action of sanitary authorities is now hampered by the conflicting views on the use of preservatives. A case recently taken before a Metropolitan police magistrate, in which 2 gr. of salicylic acid per pint were shown to be present in a drink, was dismissed with costs, although it is believed that salicylic acid in this small quantity may have injurious effects on digestion. Local authorities can at present only take legal proceedings against the retailer, although it is in most cases the manufacturer who actually adds the preservative. The recommendations of the Departmental Committee have been regarded in certain quarters indeed as establishing a sort of right on the part of food dealers to add chemicals. Dr. REGINALD DUDFIELD

(Paddington) reports that the routine addition of any chemical preservative to foodstuffs is unnecessary in these days of rapid transit, and would limit their use to special cases under stringent regulation. While admittedly the quantity of any drug used for preserving, taken with one food, is likely to fall below the toxic dose laid down by the Pharmacopœia, nevertheless the effect of preservatives on the digestive tract may still be deleterious. The action of some of these is known to be cumulative while individuals are intolerant to others, and their effect is especially liable to fall on sick persons and young children. Moreover, the danger is always present that preservatives may be used to disguise incipient putrefactive change or to counteract the results of lack of care in preparation. It would be easy, as Dr. DUDFIELD points out, to construct an imaginary meal which should contain an amount of preservative much in excess of the pharmacopœial dose of the drug used.

Evidently the time has come when further inquiry is advisable into the subject of preservatives in food, particularly in view of the wider use made of many of the articles since the 1901 report. The Ministry of Health has already, of course, power to make regulations under the 1907 Act, but the hands of the Ministry would be strengthened by exact knowledge of the effect of adding preservatives (a) on the food itself, with special reference to vitamin content, and (b) on the consumer. An investigation of this nature might be referred to the Medical Research Council with liberty to make inquiry as to methods of preserving food other than the addition of chemicals. A number of manufacturers now use no preservatives, and the ignorance among those who do use them as to the quantity required is pertinently shown by the wide range of a table published in Dr. DUDFIELD'S report, where he summarises the replies received from 95 sanitary authorities. At present control of preservatives is too largely dependent on the views of individual magistrates, some of whom take up an enlightened attitude, while others are apparently indifferent to the risks involved. The uncertainty whether magistrates will accept or reject the recommendations of the Departmental Committee has paralysed the efforts of sanitary authorities to the extent that in five administrative counties and 13 county boroughs no sampling whatever has been done for the discovery of preservatives during recent years. We are indebted to these two medical officers of health for pressing upon the community a matter of great importance to the public health.

THE TEACHING OF OBSTETRICS AND GYNÆCOLOGY.

AN addition to the series of Reports on Public Health and Medical Subjects, which is being published at intervals from the Ministry of Health, is written by Dr. Janet Campbell, senior medical officer for maternity and child welfare to the Ministry, and consists of notes on the arrangements for teaching obstetrics and gynæcology in the medical schools. This is the first time that a complete review of the subject has been published, and our readers will find it a valuable survey. They must be familiar with the numerous criticisms which have been recently, and many of them justifiably, passed upon the methods of instruction in these subjects, and we propose to deal at length in a forthcoming issue with Miss Campbell's conclusions and recommendations.

Annotations.

"Ne quid nimis."

TRAVEL AND INFECTION.

THE U.S. Public Health Service *Bulletin*, No. 129, on Communicable Diseases and Travel, written by Dr. Thomas R. Crowder, contains matter useful for the education of the public in modern ideas of how infection is spread. In an introduction, Dr. Victor Heiser emphasises the change in the problem brought about by swift steamships, trains, and airships, and alludes to Dr. Crowder's long experience in railway and steamship sanitation. In an appendix are given the Interstate regulations, promulgated by the Secretary of the Treasury, governing the transportation from State to State of persons infected with communicable diseases. In 1920 a Standard Railway Sanitary Code was approved by the U.S. Public Health Service and recommended for adoption by all the 48 States. Up to the present 20 States have adopted it. This is an important step towards uniformity. Briefly, the regulations forbid the travel of persons suffering from plague, cholera, yellow fever, typhus fever, and small-pox, and allow persons suffering from other infectious diseases to travel under proper supervision. Putting aside tuberculosis and venereal diseases, proper supervision means the conversion of one part of the train into an isolation cubicle with a skilled attendant in charge of the patient, and adequate arrangements for dealing with infectious discharges and food utensils, and for cleansing the improvised "hospital cubicle" after use. It is obvious that conditions are quite different with us and that the need for persons ill with infectious diseases to be conveyed by train very seldom arises in our densely populated country, since infectious diseases hospitals are everywhere within easy reach by motor ambulance. In discussing the reasons for the regulations, Dr. Crowder deals with many points of universal interest. For example, "fomites" are relegated to a place of small importance, and contact with infected secretions while they are still fresh and virulent is regarded as the essential danger. Dr. Crowder points out, however, that "to control the habits of the individual to the end that he may not contaminate with his secretions the things that are about him is a very difficult matter." Dr. Crowder shows that the travelling of consumptives in search of a climate that may cure them is a serious consideration. The National Tuberculosis Association estimate that annually 10,000 consumptives who are hopelessly diseased go into the West to die. Many other hopeless cases return home to die from the West. Many travel about from one resort to another. Dr. Crowder does not think the danger is great either from the "spray" of a tuberculous traveller or from the car and its furnishings after the tuberculous traveller has left it; the danger is greatest to children from their exploring habits and consequent hand-to-mouth infection. Statistics in the U.S.A., so far as they go, show lower tuberculosis death-rates among the railway employees on passenger trains than among those on freight trains. It appears that the things to be avoided are large doses of tubercle bacilli and their frequent repetition.

The regulations of the Standard Railway Sanitary Code apply to pulmonary tuberculosis and prescribe the use of a sputum cup, gauze paper for coughing into, a bag for soiled paper, the obligation to destroy this paper afterwards, and so on, but obviously the carrying out of these precautions depends upon the sanitary conscience of the tuberculous traveller. Lepers may travel with an attendant and under the usual isolation restrictions provided they have a permit from the Health Department of the States from which and to which they are travelling. Notified cases of venereal disease require permits, chiefly for the purpose of securing continuity of treatment. In discussing the danger from syphilitic sores, Dr.

Crowder says that the common drinking cup and common towel "now fortunately belong to the past." That is not so in this country, and common towels may still be seen in the lavatories of London hotels and restaurants of quite good standing. Dr. Crowder thinks the transmission of venereal disease by the toilet seat is probably a rare occurrence. The regulations in America have to make provision for cases of infectious disease discovered en route, perhaps on long journeys and far away from a hospital. Owing to the prohibitive cost and the very different circumstances obtaining in this country, arrangements for the travelling of persons suffering from ordinary infectious diseases are hardly likely to be made, but this *Bulletin*,¹ as a statement of the modern view as to how infection is spread, is well worthy of perusal.

THE FELLOWSHIP OF MEDICINE AND POST-GRADUATE TEACHING FOR LONDON.

At a meeting of the Fellowship of Medicine, held on April 13th at the Royal Society of Medicine, a scheme brought forward by the non-undergraduate hospitals in London was accepted and immediate steps will be taken to put it into operation. It is devised to meet the needs of two classes of post-graduate students—namely, those requiring short general "refresher" courses, and those requiring advanced courses in the special departments of medicine and surgery. It is proposed to arrange the former courses on the group system, centred on a general non-undergraduate hospital, to be affiliated with special hospitals in its neighbourhood, and each group should be responsible for three or four such courses during the year. It is hoped that four, or perhaps five, of these groups will be founded in London. The programme will be begun by a course at the Prince of Wales's General Hospital, Tottenham, assisted by the special hospitals belonging to the North-Eastern group, from June 11th to June 23rd. Further details regarding this course, and others to follow throughout the year, will be published shortly. For graduates requiring more advanced instruction it is proposed that each of the special hospitals should undertake two or three courses during the year, and it is hoped that specialists from the undergraduate hospitals will be willing to come to the special hospitals on the invitation of the staff, and to assist in lectures and demonstrations.

THE PHYSIOLOGICAL EFFECTS OF EXPOSURE TO LOW TEMPERATURES.

In a recent communication to the *Quarterly Journal of Experimental Physiology* (Vol. xiii., No. 1), S. W. Britton describes experiments on the effects of lowering the temperature in homoiothermic animals. The cooling apparatus employed is described and practically all the results were obtained on cats placed in a double-walled chamber, at a temperature of 5° to 8°. In the process of lowering the temperature of these animals there is a progressive paralysis of the central nervous system. In recovery a definite order of reappearance of reactions occurs at different deep rectal temperatures—e.g., knee-jerk and micturition reflexes, 16°; shivering reflex, 19.5°; clawing and winking reflexes, 21.5°; light reflex, 23°; equilibrium, sight, smell, and hearing, 27.5°; and coördinated action (walking, &c.), 28°. In the initiation and subsidence of stepping movements at low temperatures, a definite march or order is observed. A regular alternation between shivering and inspirations occurs between 22° and 24°. Exaggerated tonic spasms of the postural musculature occurs when the temperature of the recovering animal stands between 21° and 25°. In its progressive effects gradual cooling shows a strong similarity

to the induction of anaesthesia, consciousness becoming abolished gradually and finally disappearing between 27° and 25°, while the ordinary reflexes are still maintained (24°–19°). At low temperatures (19° or 20°) the pupil becomes contracted, to dilate widely just before death. No condition resembling "artificial hibernation" can be said to occur when a homoiothermic animal such as the cat is reduced to very low body temperatures; a definite thermogenic ability is retained even at 19°, from which temperature spontaneous recovery is effected in 10 to 12 hours. The activities of the heart, respiratory muscles, and abdominal viscera are probably wholly responsible for an initial small rise in body temperature, but spontaneous shivering and stepping movements and an exaggerated muscular tonicity occurring about 20° are the chief factors in heat production and hence in recovery of the animal. So far as the author could determine, death from exposure to cold is due to paralysis of the respiratory centre in the medulla oblongata.

THE NEED FOR MORE AMBULANCES.

The circumstances at a recent inquest held by the coroner for Westminster have led to a wide discussion in the press as to the need for more ambulances in the metropolis, but many of the suggestions made have shown unfamiliarity with the present position. The three authorities in London who direct ambulance services are the London County Council, the Metropolitan Asylums Board, and the St. John Ambulance Association, each authority catering for a separate and distinct type of case. The London Ambulance Service, directed by the London County Council, conveys, at any hour of the day or night, persons suffering from accident or sudden illness from the streets or public places, such as railway stations, theatres, factories, and workshops, to hospitals, infirmaries, or their homes. Although cases of accident occurring in private houses are accepted, the service is not intended for the removal from private premises of persons suffering from illness; when, however, in such a case the caller states that the life of the patient would be endangered failing immediate removal to a hospital, the call is at once accepted. The Metropolitan Asylums Board service deals with all cases of infectious illness, while the St. John Ambulance Association deals in consultation with the police with first-aid cases arising out of processions and public ceremonies. Both these services also convey cases of non-infectious illness where there is no urgency. The County Council ambulance service is served from seven stations, and the establishment of three additional stations has recently been authorised; it is hoped that when the latter are in use the time taken to reach cases (average during 1922, 8.7 minutes) will be considerably reduced. At each station a motor ambulance, equipped with first aid appliances and with a crew of two trained attendants and a driver, is constantly in commission, while during the busy hours of the day two stations have an additional ambulance. Although the majority of telephone calls are given by the police, a private individual can summon an ambulance. The telephone exchange is asked for "Ambulance," and no number is required; the place of the accident or illness should be stated, together with the caller's name. No charge is made for the call or for use of the ambulance. Since the inception of the service the number of calls has steadily increased from 2405 in 1915 to 23,966 in 1922; the average daily number of calls is now about 70. The chief officer of the London Fire Brigade is the officer-in-charge of the Ambulance Service, which is directed from the headquarters of the Brigade in Southwark Bridge-road, S.E. 1. The operative staff numbers 97. The estimated cost of the service for the year ended March 31st, 1923, was £34,470.

The case we have quoted may be added to other recent incidents which call attention to the insufficient

¹ Government Printing Office, Washington. 10 cents.

number of ambulances available for cases of sudden need in the vast area of London. Until more ambulances are available it is clear that there must be regulations for restricting their use. There would certainly have been justifiable complaint, for example, had a person run over by accident in Trafalgar-square been kept lying in the road for a quarter of an hour or more, because a policeman had authorised the use of an ambulance to convey from his hotel to a hospital a well-to-do citizen who was afterwards found to have little the matter with him. For a medical man to vouch for the urgency of a particular case is, of course, a different matter; and it must be remembered that in the case referred to above when the ambulance was summoned it came at once. Moreover, if the public demand the provision of more ambulances the public must be prepared to pay for them, recognising, on the one hand, that they are costly to purchase and will not be continually in use, and, on the other hand, that a better service will ensure more rapid attention and save more lives.

HENRY ARNOLD BECKETT.

NEARLY 30 years ago there died, while at his work, in the office of THE LANCET, Mr. Henry Arnold Beckett, who had been connected with the paper, first in the printing, and later in the editorial departments, from boyhood. The announcement which has recently been made that THE LANCET would celebrate its centenary in the autumn of this year, has brought us a letter telling us that the elder sister of the late Henry Beckett is still alive and that her hundredth birthday follows by only a few weeks the hundredth birthday of THE LANCET, she being some two years older than her late brother. Beckett's association with THE LANCET was an extremely intimate one. He was brought over from the printing department by the original Thomas Wakley, who had been attracted by his extraordinary gift of memory. He was made a sort of universal proof-reader for the Editor, and in the course of his duties became an absolute dictionary of information on professional subjects. He knew the names, addresses, qualifications, and professional and literary records of hundreds of medical men. He supervised the indexing of THE LANCET for years, and his recollection of the contents of back numbers was extraordinary. He had no medical training, but a wide, if theoretical, knowledge of medical science had been obtained in two ways. First, his large and variegated reading was so carefully performed, and with such attention to the author's meaning, that much of the essential teaching was made his own, and was ready for addition and modification. Secondly, the interviews which he had had with medical authors concerning the contents of their papers were always turned by Beckett into opportunities for increasing or revising his knowledge. On the occasion of his death many letters reached us from contributors to our columns acknowledging indebtedness to Beckett for important literary assistance.

THE ABORTIVE TREATMENT OF SYPHILIS.

In a paper read at a meeting of the Nordisk Dermatologisk Forening in Stockholm and published in *Hospitalstidende* for Feb. 21st, Dr. H. Boas has given an account of his experiences of the abortive treatment of syphilis. Such abortive treatment he defines as the radical cure, by one or more courses of treatment, of syphilis in its first stage. The first question to be asked in this matter is: When can it be said with certainty that abortive treatment has effected a radical cure? The answer is tantalising: The only reliable evidence of a radical cure is, in the experience of Dr. Boas, reinfection. Without this retrospective evidence of a complete cure, the patient cannot be assured of recovery, however early and thoroughly he may have been treated. All may seem to be well after such early treatment, but years later—even as

many as seven years later—a relapse may occur. All the patients included in Dr. Boas's statistics were observed for two years or more after the completion of treatment. The first series consisted of 245 patients, each of whom was given one intramuscular injection of 60 cg. of salvarsan, one intravenous injection of 40 cg. of salvarsan, and 50 inunctions of mercury. Of these 245 patients, 153 were Wassermann-negative and 92 were Wassermann-positive before the institution of treatment. Among the Wassermann-negative cases there were 12 relapses, and among the Wassermann-positive cases there were 10 relapses from six months to between seven and eight years after treatment. In a second series of cases there were 75 patients, each of whom received one intramuscular injection of 60 cg. of salvarsan, one intravenous injection of 40 cg. of salvarsan, 50 inunctions of mercury followed by intermittent mercurial treatment for three years. There were 47 Wassermann-negative and 28 Wassermann-positive cases in this series and, curiously enough, the four patients who relapsed all belonged to the group that was Wassermann-negative before specific treatment was instituted. In a third series of only 22 cases, each patient was given four injections of silver salvarsan (15, 20, 25, and 25 cg.), 50 inunctions of mercury, and intermittent mercurial treatment for three years. In this series no relapse had occurred within two to three years of treatment. Dr. Boas considers as quite unwarrantable the opinion of certain German authorities who have taught that when the patient is clinically and serologically symptom-free for two years after a course of abortive treatment, he may be considered as perfectly cured. He may be, but he cannot feel sure. It is not yet certain that supplementing the original course of abortive treatment with salvarsan and mercury by intermittent mercurial treatment for three years adds appreciably to the chances of eradicating the disease, but Dr. Boas is inclined to favour this three-year course, although the guarantee it affords is not absolute.

COMPOSITION AND STYLE.

HE who puts forth a treatise, however modest, on composition and style, and he, however informed, whose task it is to review such a work, are alike in the position of egg dancers—surrounded by traps which it is their duty to escape. Even such an expert as Sir Clifford Allbutt in the use and arrangement of words, so well-versed an exponent of the finest method of delivering a literary message, may break a yolk; but those who attempt to sit in judgment may make an omelette. However, in this admirable little book¹ we have found but one slip in the middle of most valuable counsel to medical writers. That the style of writing in many scientific papers is often bad is the sad truth. To express ideas and experiences in a lucid manner is by no means an easy task, and many a scientific paper whose matter is excellent loses value because the writer has not learned to convey his knowledge to others. "Have something to say, and say it as clearly as you can. That is the only secret of style," was the dictum of Matthew Arnold to G. W. E. Russell, but *belles lettres* only were in question. Writers of scientific papers must all be credited with something to say, not for its beauty or æsthetic qualities but for its utility. Therefore the actual matter is not adaptable or flexible. All the more necessary is it that the something should be said clearly, and a study of Sir Clifford Allbutt's book will be of the first assistance to the acquisition of the desired clearness. He tells authors what to avoid and at what to aim, and in one instance at least has himself fallen into the pit. Under the heading "Precision," he writes as follows: "The seat among the immortals of letters prepared for Tennyson may, for its ungainliness and its antics, be denied to the more vivid and penetrating muse of Browning." It

¹ Notes on the Composition of Scientific Papers. By the Right Hon. Sir T. Clifford Allbutt, K.C.B. London: Macmillan and Co. 1923. Pp. 187. 6s.

is not difficult to see Sir Clifford Allbutt's meaning, but in strict grammar he has made that stationary thing, a seat, rise and gambol. We point to this sentence as an example of how fatally easy it is, even in a treatise on composition, to fall into error. Is there not the classic example of the schoolmaster who wrote on the black-board, during a lesson on composition, "Never use a preposition to end a sentence with."

This is the third edition of a work which has proved valuable and suggestive to many. The sections on the misuse of words and on the use of simple words, are particularly admirable and remind us how many of the great passages of English literature are made up almost entirely of words of one syllable. The Prayer Book version of the Psalms, which we trust will be spared to us, is full of such, and so is the Authorised Version of other Books of the Bible, to take one example from either: "I will lift up mine eyes unto the hills from whence cometh my help"; and again, "Come from the four winds, O breath, and breathe upon these slain, that they may live." It is by studying language such as that, and also by reading the works of the masters of scientific expression such as Newton, Huxley, Faraday, Tyndall, Watson, and Trousseau, among the dead, that a writer of scientific papers may learn to express himself so as to impart his knowledge to others. We decline the task of selecting living models; it would be as arrogant a proceeding as an attempt to indicate which of the leaders now with us hardly do their matter justice in the form in which it is presented.

ANTI-ANTIBODIES.

WHEN it was first realised that the introduction into an animal of a native proteid coming from any other species of live thing was often followed by the production of specific antibodies, people toyed a good deal with the idea that the reaction might lead to great complexities. If the host produces antibodies to the proteids of the parasite, it was not unnatural to assume that the parasite might elaborate antibodies to the proteids of the host and, among others, to the host's antibodies. To these anti-antibodies produced by the parasite, the host would presumably reply with anti-anti-antibodies, and so on indefinitely. There was, then, and is now, no reasonable doubt that antibodies are proteids or closely associated with proteids, but it seems that they cannot be identified as such by the fact that they excite the production of antibodies. Dr. S. P. Bedson, of the Lister Institute, has recently¹ examined a supposed instance of the occurrence of these anti-antibodies.

If a rabbit is repeatedly inoculated with the blood platelets of guinea-pigs its serum develops plate-lytic properties and causes purpura when injected into guinea-pigs. If a guinea-pig is given a quantity of this serum sufficient to cause symptoms but not large enough to kill it, and is then left for a fortnight or so, it is then found to be more resistant than normal guinea-pigs to the injection of the rabbit lytic serum. It has been supposed that this acquired immunity is due to the production by the guinea-pig of an antibody to the platelet antibody made by the rabbit. Dr. Bedson shows, however, that the phenomena can be reproduced if the first injection is the serum of a normal rabbit. The resistance to the second injection must therefore be supposed to be simply resistance to rabbit proteid, not rabbit antibody. Since antibody is associated with proteid, the former necessarily involves the latter. No evidence is obtained that the rabbit antibody is a new proteid substance. It might be and yet fail to arouse the formation of specific antibody. But it seems more probable that the antibody, which for convenience is spoken of as a special substance, is really only a special property of a normal serum proteid. Of the existence of antibodies as substances rather than properties there is, indeed, no

evidence at all; if they are not separate substances they cannot lead to the production of separate and demonstrable antibodies.

If, then, the anti-anti-reaction fails as between two mammals—the group in which the capacity for antibody response is most highly developed—there is still less reason for supposing that anything of the kind occurs in the relations between a relatively elementary parasite and a mammalian host. For the antibody response to proteid from a different species is not a general property of living matter; it is very poorly represented in invertebrates generally, and its existence among bacteria and protozoa has never been demonstrated any more than in plants. It is now realised that bacteria protect themselves against mammalian antibodies by using their vast numerical abundance and capacity for rapid multiplication to breed out resistant races. They achieve immunity to antibodies, but it is effected by entirely different methods to those used by their sparse, slowly-breeding hosts, and it is racial rather than individual.

FRENCH HOSPITALITY FOR FOREIGN COLLEAGUES.

MEMBERS of the medical profession travelling in France and wishing to study the French practice of medicine will find in the Association pour le Développement des Relations Médicales (l'A.D.R.M.) a useful guide and friend. It was established in 1920 and has grown in importance ever since. Its governing body consists of 40 members recruited from the most notable persons in the French medical profession, with Prof. Hartmann at its head. Its original aim was to help members of the medical profession, coming from allied and friendly countries, to Paris. A Bureau has been organised to supply visitors with information, and it has served this purpose so well that it has rapidly extended its activities, and has become an institution (1) for promoting the expansion of French medical science; (2) for establishing relations between French universities, societies, and journals with similar institutions abroad; (3) for encouraging the exchange of professors and other representatives; and (4) for paving the way for foreign doctors and students wishing to study in France. The Association has its headquarters in the Bécлар Room of the Faculty of Medicine, and every morning and afternoon on week days visitors can obtain not only special information with regard to medical subjects, but also useful hints as to such practical matters as hotel charges and pension accommodation. All this information is given free of charge. A pamphlet, *l'Enseignement médical à Paris*, costing 1 franc, will give the medical visitor information as to: (1) the faculty of medicine and the hospitals; (2) medical teaching courses, including libraries and museums; (3) institutes and schools attached to the faculty; (4) clinical teaching in the hospitals; (5) complementary and post-graduate courses. The pamphlet contains a large plan of Paris with a key index of the hospitals. The telephone number of the Bureau is Fleurus 07-16.

SUDDEN DEATH FOLLOWING THORACENTESIS.

ACCORDING to Dr. Ernest S. Du Bray,¹ instructor of medicine in the University of California Medical School, San Francisco, cases of syncope, collapse, and death can be classified in three groups. In the first group of cases, as Capps has shown, the symptoms are neuro-genic, being due to a pleural reflex. In such cases syncope during aspiration is caused by direct cardiac inhibition from irritation of the pleural or pulmonary nerves by the trocar or by congestion. It is commonest towards the end of the operation when the instrument is most likely to scratch the pleura and when the lung is most congested. Syncope occurring within 48 hours after aspiration is probably due to the circulatory

¹ Journal of Pathology and Bacteriology, vol. xxvi., p. 176.

¹ American Journal of the Medical Sciences, March, 1923.

reflexes arising from congestion of the lungs. Syncope during irrigation of the pleural cavity is the result of a reflex arising from chemical irritation of the pleura. A second group of cases is always associated with demonstrable anatomical lesions of the lung parenchyma either in the form of laceration or punctured wounds caused by the trocar or definite pulmonary congestion of an extensive grade. This group includes cases of air embolism of the cerebral vessels and cases with well-marked signs of acute pulmonary oedema, which usually supervenes after drainage of the pleural cavity, though it may occur after simple exploration. The exact mechanism of this acute pulmonary oedema is still unsolved. Pulmonary thrombosis following lung puncture with resulting cardiac or cerebral embolism may also cause untoward symptoms. In this mixed group it is probable that several factors combined account for collapse in most instances. The third group of cases is that associated with the occurrence of accidental pneumothorax. Dr. Du Bray, however, is of opinion that many of the fatal cases ascribed to this cause would probably be better explained on the basis of the pleural reflex or pulmonary injury and congestion. In the case observed by himself, which occurred in a woman aged 23, the autopsy showed that collapse during exploratory puncture and subsequent death of the patient within 12 hours were not produced primarily by the pleural reflex or by the rapid production of accidental pneumothorax, but by a puncture wound in the middle of the right lung, which was surrounded by hæmorrhage and congestion associated with extensive pulmonary oedema.

THE REMUNERATION OF POOR-LAW MEDICAL OFFICERS.

THE recent circular issued by the Ministry of Health (Circular 382) on this subject contains information of importance to a large number of medical practitioners. By its instructions medical officers under this service in many instances will have their bonuses brought into salary, and their salaries are thus standardised or stabilised for the next few years. The Ministry do not desire a statement to be submitted to them respecting the changes in salary unless an increase of expenditure is required. Increases will not, as a rule, be considered more frequently than once a year or on a general consideration of the position—e.g., when it is proposed to revise salaries on a post-war basis instead of continuing to remunerate them by means of salary and bonus. In many instances—the number of these is unknown but is large—boards of guardians refused any bonus additions to the salaries of their medical officers during the war and after. In some instances it was alleged, in this connexion, that the operation of the National (Health) Insurance Act has in considerable measure transferred former medical work under the Poor-law to practitioners under the Insurance Act, and in other instances that war conditions, with their abundance of employment, had still further lessened the work of district medical officers. Whatever degree of importance attached to these contentions at the time they were made, conditions in this and last year have more than reversed the balance; and at the present time we have no doubt that older district medical officers would state that, although the general public health is good, their work is as great as say a quarter of a century ago. The amount of work necessitated for the unemployed, and still more for their dependents, has had a marked influence in increasing district Poor-law medical work. Furthermore the work of the district medical officer in certifying patients for admission to infirmaries has greatly increased, especially in towns, in part owing to the satisfactory fact that these infirmaries are gradually becoming recognised as general hospitals for the wage-earning classes, especially for cases not of a very acute type, which cannot be satisfactorily treated at home. We understand that at the present

time an attempt is being made to collect and analyse information and thus help in securing the standardisation of salaries of district medical officers and of part-time resident medical officers of infirmaries in relation to the amount of work done.

The whole subject calls for exhaustive consideration as part of the larger question of consolidation of public medical services. Meanwhile we welcome the implied insistence in the circular of the Ministry of the condition that no medical officer's salary shall be reduced without their consent. We wish they had gone a step further and insisted on the regularisation of the situation of medical officers whose appointment is "temporary." This continues to be one of considerable hardship.

DEATH CERTIFICATION.

A BILL to amend the law relating to Coroners' Law and the Certification and Registration of Deaths and Burial was ordered by the House of Commons to be printed last February and may come up for reading to-day (Friday). It is largely based upon the representations of a committee of the British Medical Association, and it deals with many of the defaults and anomalies which all medical men know to exist to-day. Death certification is a matter of the first importance to the public and the medical profession, and many public officials have pressed for reform in the existing procedure. The Bill provides, *inter alia*, that, while the Registrar cannot proceed under Section 17 of the Births and Deaths Registration Act, 1874, until he has received a medical certificate of death, such certificate must be given by a registered medical practitioner who has viewed the body, being either the practitioner who certifies the cause of death, or the practitioner who has attended the deceased in his last illness, or, failing these, a special medical officer. The appointment of the special medical officer is to be made by the council of either county or borough "for the purpose (where the coroner shall so direct) of investigating and reporting to him upon the cause of death of the deceased." The fee to registered medical practitioners and special medical officers in respect of certification, for the certificate of death, will be 2s. 6d., with an additional fee of 2s. per mile without the radius of a mile. The fee for the certificate of cause of death is also 2s. 6d. The fees to registered medical practitioners and special officers payable by the coroner are in a further schedule, and run as follows: For a report to the coroner that death has arisen from unnatural causes 10s. 6d., and £1 1s. for any further report required by him; for making by the direction of the coroner a post-mortem examination, whether an inquest be held or no, £2 2s., if without an analysis of the contents of any organ, while for such an analysis an additional fee not exceeding £5 5s. will be paid on the coroner's direction. For every day of attendance to give evidence on the summons of the coroner £1 1s. will be paid.

A section dealing with the report to be made to the coroner, where the circumstances are suspect or where the medical certificate is withheld, runs as follows:—

"Where a medical practitioner has attended a deceased person in his last illness, or has attended at a birth of a still-born child, it shall be the duty of such practitioner within 24 hours after he has become aware of the death, or after the birth has occurred, to sign and deliver to the registrar in a sealed envelope a medical certificate of the death or still-birth (as the case may be), and (in a case of death) either to deliver as aforesaid a medical certificate of the cause of death, or if such cause be unknown to him, or if he shall be of opinion that the death is directly or indirectly arisen from, or been accelerated by violence, neglect, poison, or other unnatural cause, to report the circumstances of the death and his opinion thereon to the coroner for the district in which the death occurred."

A heavy penalty is placed upon error or default, for any practitioner who fails to comply with the provisions there set out will be liable for each offence to a penalty not exceeding £20.

THE WORK OF THE GENERAL NURSING COUNCIL.

THE General Nursing Council is settling down to its proper work. The Nurses Registration Act of 1919, which placed the nursing profession on a legal basis, granted it the privilege of electing its own governing body, and the first election of this Council, composed of 16 registered nurses, together with five representatives of the Ministry of Health, two representatives of the Board of Education, and two medical practitioners, took place last January. The nominated Council, which served from 1920 to 1922, had an uphill task in its endeavours to set up machinery designed to bring about standardisation and order amongst a large body of workers where practically no standards had hitherto prevailed. The most important work before the new Council must be of an educational nature, for until a sound foundation of education is laid the profession of nursing cannot be said to be securely established. The hospitals which supply the material for training are so varied in character that it is not easy to establish a uniform standard of education. The task, although formidable, is one which can be surmounted, and the General Nursing Council is inviting the hospitals which provide treatment of a specialised nature to submit schemes for the general training of nurses in which such special hospitals may be included. The Council has wisely omitted to state a minimum number of beds which shall entitle to receive recognition as a training school; evidence must be produced that work in that hospital can supply adequate material for training, and that the hospital is justified in entering its nurses for a prescribed State examination. It is now for every individual hospital to see that its nurses are adequately trained in the care of the sick and taken through a part or whole of the curriculum prescribed by the Council. The conduct of the qualifying examination and the establishment of a panel of examiners will demand much attention, since the standard of the trained nurse ultimately rests with the trained examiner. The General Nursing Council has brought out the first State register of nurses, but that is only a beginning. The standard laid down for the registration of existing nurses has been criticised as inelastic, but it should be remembered that a rule whereby nurses practising before 1900, and still in practice in 1919, are eligible to apply for registration, is now before the Minister of Health for his approval. Whether this extension is sufficient is doubtful, and a more generous interpretation of the Act may yet be necessary. Other questions now before the Council are the protection of the State registered nurses' uniform, the misuse of which in the future will be a penal offence, and the fixing of examination fees for future nurses.

SUMMER time starts in this country from next Sunday, April 22nd, at 2 A.M., and ends on Sunday, Sept. 16th.

AT a meeting of the London licensees of insulin with the Medical Research Council on Friday, April 6th, the suggestion was discussed that the Medical Research Council should issue an official announcement with regard to present supplies of insulin of British manufacture, intimating that arrangements have also been made for the distribution of temporary supplies of insulin of American origin. Messrs. Burroughs Wellcome and Co. deferred therefore the communication that supplies of their own manufacture have been issued. "Wellcome" Brand Insulin is manufactured throughout by Messrs. Burroughs Wellcome and Co., and we are informed that a batch of insulin produced at the Wellcome Physiological Research Laboratories some time before Dec. 1st, 1922 (for which date the Medical Research Council called the first informal conference with the manufacturers to discuss the production of insulin), proved satisfactory on test.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

XVI.

THE TREATMENT OF PRIMARY OR SPASMODIC DYSMENORRHOEA.

THE effective treatment of dysmenorrhœa depends upon a correct recognition of the variety and of the conditions causing the excessive pain. It may be divided into two main classes—namely, pain with, and pain without any accompanying disease of the pelvic organs. The dysmenorrhœa most commonly met with in young girls or in sterile married women is the so-called primary or spasmodic variety without any disease of the pelvic organs.

The exact causation of the primary or so-called spasmodic dysmenorrhœa is uncertain, but the working hypothesis, which accords best with the facts, is that it is due to spasmodic rigidity of the sphincter muscle at the internal os accompanied by colicky uterine contractions.

General Treatment.

The first step to be taken in undertaking the treatment of a case of dysmenorrhœa is a careful investigation into the state of the patient's general health, her mode of life and surroundings. In the event of any general condition such as anæmia, chronic dyspepsia, or tuberculous disease being found, the treatment of these must first be undertaken. The two conditions most frequently calling for alleviation are anæmia and constipation, the first increasing the pain by diminishing the menstrual flow, a common clinical history being that the freer the flow the less the pain, and the second increasing the pain by producing pelvic congestion. In the same way such unhealthy conditions as overwork, standing for many hours, improper or insufficient food, the abuse of alcohol must all, if possible, be corrected. The lack of success that so often attends the treatment of hospital out-patients may be due to the failure on the part of the physician to recognise these factors or inability on the part of the patient to correct them.

Treatment may have to include, when possible, change of occupation, change of surroundings, more care at the periods, especially in the case of young girls at school.

Exercise and Baths.—The taking of a proper amount of exercise in the fresh air is important, and young girls often require advice as to the precautions they should take when the period is present. While for a healthy girl with no undue amount of pain it is unnecessary to alter her ordinary habits during the period, for those who suffer undue pain, rest is essential, and excessive exercise or the playing of games must be forbidden. The provision of a sufficient amount of sleep in properly ventilated rooms is important. All young girls should be advised to take hot baths during the whole of the period, and this habit should be acquired from the very commencement of their menstrual life. Care must be taken to avoid chills, and cold baths or bathing must, of course, be prohibited. The practice of taking hot baths certainly tends to lessen any pain that may be present, and is both cleanly and hygienic.

Constipation undoubtedly has a most baneful effect upon dysmenorrhœa, producing as it does pelvic congestion and marked pressure from scybalous masses on the uterus and ovaries, so that in every case it is essential to regulate the bowels, and not to be content to rely simply on the use of aperients or enemata. The patient should be ordered a proper diet containing an excess of vegetables, fruit, salt, and water. Many young women habitually drink too little; a sufficiency of fluid is essential if constipation is to be overcome. The patient should be told to try to have her bowels open at the same hour every day,

even if there is no desire to defæcate. Commonly, the first result of such an order is no action of the bowels for several days, yet no aperient should be allowed, and the patient should be assured that relief will ultimately and surely be obtained. It may be necessary to help matters by the administration of liquid paraffin as a lubricant. If this treatment fails to act, then one of the milder aperients, such as cascara sagrada, should be given in small doses every day, not in large doses occasionally. If it is obviously the lower bowel which is at fault, then this may be emptied regularly each day by small enemata, but the régime should be persisted in and the enemata given up as soon as possible. It is particularly when the dysmenorrhœa is associated with severe headaches and vomiting that the treatment of constipation is so important. If cascara sagrada disagrees, recourse may be had to one or other of the simple laxatives, to be taken with the paraffin, such as sulphur, senna, aloes, figs, or an effervescent saline mixture. Whenever possible, however, aperients should not be solely employed, and as adjuvants the importance of regular exercise and the use of abdominal massage should not be lost sight of.

Treatment of the Pain.

In any severe case of primary or spasmodic dysmenorrhœa the first and most important thing is for the patient to go to bed. If this is impossible it is much more difficult to obtain relief from the pain. Warmth should be applied to the lower abdomen and back by means of hot-water bottles. If possible, the patient should be put into a hot simple or mustard hip bath, or small enemata may be given as hot as can be borne and retained as long as possible. These may be simple enemata of hot water alone, or may contain such drugs as potassium or sodium bromide 20-30 gr., chloral hydrate 20 gr., chlorotone 10-15 gr., especially when vomiting is a marked symptom, or antipyrine 15 gr., suspended in a small quantity, say 4 oz., of hot mucilage of starch.

In the treatment of the pain by the internal administration of drugs most reliance is to be placed upon the coal-tar derivatives, such as antipyrine, phenacetin or aspirin in doses of 10-15 gr. of each, or pyramidon 5-8 gr. Antifebrine has so often given rise to poisonous symptoms that it should not be employed. These drugs should be combined with small doses of caffeine citrate, in the strength of 1 gr. to every 5 gr. of the drug ordered, to lessen their depressant effects.

One of the most successful methods of treating these cases is by the administration of atropine. Atropine has a markedly sedative effect upon the movements of the stomach and intestine; after small quantities of aperients the normal peristaltic action is not affected, but the griping pains resulting from large doses or from the more violent purgatives are absent if atropine is given along with them. (Cushny.) The same sedative effect is seen in the case of the uterus, and here again the drug acts best when the muscular contractions are irregular and excessive. It is not surprising then to find that the administration of atropine produces good results in the treatment of primary or spasmodic dysmenorrhœa. The treatment should be commenced some few days before the expected onset of the period, and 1/100 gr. may be given in tablet form three times a day, and the dose may be increased if necessary, provided the patient tolerates the drug well. Benzyl benzoate has been suggested as a drug possessing a similar action to that of atropine and as less likely to produce toxic symptoms. It may be given in the form of an emulsion as follows: benzyl benzoate, 15 gr.; mucilage of acacia, 1 drachm; aromatic elixir, 1 oz., in a dose of one-half to 2 drachms every two hours as required. Many other drugs have been recommended and are still used in the treatment of dysmenorrhœa—for example, apiol, hydrastis canadensis, viburnum prunifolium, gelsemium, cimicifuga, pulsatilla, cannabis indica, and others. The three drugs which should never be ordered if they can possibly be avoided are alcohol, morphia, and cocaine.

Alcohol undoubtedly has a considerable effect in relieving the pain, and it is an old-fashioned remedy, but the danger of establishing the practice of drinking is so grave that it should never be ordered, and the same warning applies to morphia. If it is necessary to give the latter drug—and at times the pain is so intense that it must be used—then it should be given as a hypodermic injection only. In cases where ordinary remedies fail and the pain is not so severe as to require morphia for its relief, it is permissible to give small doses of opium in such a prescription as the following: pot. brom., 15 gr.; sal volatile, half drachm; tinct. camphor co., half drachm; tinct. zingib., half drachm; aq. menth. pip., 1 oz.; two tablespoonfuls to be given when the pain is severe. In highly strung neurotic patients the combination of one or other of the bromides with some of the anti-spasmodics mentioned is often useful.

Dilatation of the Cervix.

When, in spite of all that can be done to correct any defect in the patient's general health and medicinal treatment of the pain fails, other measures must be resorted to. The procedure most commonly adopted is dilatation of the cervix. This is done with the object of paralysing, at any rate for the time being, the sphincter muscle of the internal os, and if it is to be successful must be performed thoroughly. When we remember the probable cause of the pain it is not surprising to find that the results of this operation are not very satisfactory. About one-third of the patients are cured, another third are relieved for a varying length of time over one or more periods, and in the remainder it fails. The operation may be repeated a second time if it fails the first time, but it is not as a rule worth while doing it more than twice.

When both medicinal treatment and dilatation have failed to relieve the pain it has been suggested that subtotal hysterectomy should be performed with the object of producing amenorrhœa. This procedure in a young woman is, however, never justifiable. In many of these patients the pain ultimately is relieved either by treatment, the lapse of time, or marriage and the occurrence of pregnancy. For these reasons so serious and mutilating an operation as hysterectomy should not be performed. At the present day the same result—namely, amenorrhœa, either permanent, or, better still, of a temporary character—can be obtained by the intra-uterine application of radium. The introduction of a 50 mgm. tube of radium into the interior of the uterus and its retention there for a period of 8-10 hours will result in amenorrhœa usually lasting for 12-18 months. The first result is often an excessive period, but after this the periods usually stop gradually or immediately, and the resulting period of amenorrhœa can be taken advantage of to improve the patient's general health if necessary in the hope that when the periods return they may possibly occur without severe pain. A sufficient number of these cases have not yet been treated by radium to enable us to determine the effect upon the pain when the periods return, but this method of treatment should be given a trial in any case in preference to performing hysterectomy.

Treatment of Membranous and Secondary Dysmenorrhœa.

If the passage of the shreds or membranes is not associated with pain no treatment need be undertaken. If severe pain is present then it should be treated in the manner already outlined. Treatment of the interior of the uterus by the application of drugs or the operation of curettage yields very poor results and is not as a rule worth undertaking. If the case is one of secondary or congestive dysmenorrhœa due to disease of one or other of the pelvic organs, then it is essential to undertake the correct treatment of the underlying condition whatever that may be, and only if this is impossible should the pain alone be treated.

Obstetric Physician, University College Hospital.

Special Articles.

REPORT ON THE HEALTH OF THE ROYAL AIR FORCE, 1921.*

THERE was a general reduction in sickness for the total force during 1921. This is more marked when it is taken into account that sickness figures for India are included for the first time. The rates for India are higher than those of any other area, but in spite of this, the ratio per 1000 of strength of fresh cases of sickness has dropped from 551.8 in 1920 to 497.3 in 1921. These ratios exclude cases of sickness of less than 48 hours' duration. The average duration of each case in days (excluding 48-hour cases) fell from 48.5 in 1920 to 19.6 in 1921. This drop is partly accounted for by the fact that the war legacy of low medical category cases, which was influencing the figures for 1920, had been eliminated during the year under review. The sole increase in ratios was in the death-rate, this being 4.7 per 1000 for 1921, compared with 4.4 for 1920. The total number of deaths was 134 as compared with 115 in the previous year. The disaster to H.M. Airship R.38 accounted for 24 of the 134 deaths. Excluding these 24 deaths, the death-rate per 1000 of strength for 1921 would have been 3.9.

Venereal Disease.

Successful efforts were made throughout the force during 1921 to reduce the amount of venereal disease. The total case-incidence per 1000 of strength was 36.1 compared to 49.6 in 1920. In the report under review a new feature is the distinction made between primary cases—i.e., cases reporting for treatment for the first time after infection—and all other venereal cases. The primary rate in 1921 was 22.4 per 1000, as compared with 36.9 for 1920. An interesting chart is given showing the primary case-rates per month; the chief feature of the chart is the steady diminution shown in the case-rate over the period of two years. The reduction in the rate would appear to have been very largely effected by the energetic prophylactic measures which were carried out. These measures are described in detail in the report. An attempt has been made to estimate the value of prophylactic disinfection and the results of this investigation are shown in tabular form.

"Upper Air-Passage Infections."

The term "upper air-passage infections" has been retained, and a chart is given showing the monthly case-incidence in ratios per 1000 of strength in the United Kingdom and abroad in 1921, and in the United Kingdom in 1920. The marked differences in the graphs of the United Kingdom for 1920 and 1921, in March, April, and May is probably largely due to the varying climatic conditions of the two years. It will be remembered that the weather in 1920 was remarkable for a wet spring, but 1921 was particularly fine during that season. A table is also given which shows the monthly case-incidence in ratios per 1000 of strength in each area abroad during 1921. From this table it appears that the Mediterranean littoral (which includes Egypt, Palestine, and Malta) shows the highest rate of all areas abroad, as did Egypt and Palestine in 1920, the respective ratios per 1000 of strength being 93.4 in 1920 and 110.4 in 1921.

Deaths and Injuries.

Deaths and injuries are treated as in the report for 1920. Tables are given showing death and injury ratios among different types of units. These are further

explained in a table which shows the comparative case-rates of deaths and injury in each of the groups of units. Among the larger groups at home the main difference from the corresponding figures in the report for 1920 is the improvement in the health of personnel depôts—mainly due to the elimination of men of low medical category who were concentrated in such units in 1920. The headquarters group (consisting largely of administrative units) and personnel depôts have the smallest amount of sickness, whilst experimental units, flying schools, squadrons, and repair depôts again show the highest proportion of injury. Disease rates generally abroad are considerably in excess of those at home, which is naturally to be expected in view of climatic conditions, and it is suggested that the adverse climatic conditions abroad play some part in liability to injury, as injury rates abroad are 50 per cent. in excess of those at home.

A further table shows injuries classified by cause and nature of injury. This table also distinguishes between injuries regarded as occurring "on duty" and those "off duty." From the table it appears that in flying and propeller accidents the injuries are either general in nature or confined to the upper part of the body. In only 14 cases, out of the total of 149 due to these causes, was the lower extremity alone involved. On the other hand, the lower extremity alone was injured in 436 cases out of a total of 610 due to athletics; 431 out of these 610 cases were due to football, and of these 431 there were 109 cases of traumatic synovitis of the knee, or almost exactly one in every four cases. It is of interest that football accounted for 71 per cent. of all injuries due to athletics both in 1920 and 1921.

Fatal Flying Accidents, &c.

A new table is given which shows machine flights, machine hours, and fatal flying accidents. From this table it appears that although the fatal accident risk for each flight was lower at home than abroad, a larger number of hours was flown abroad for each fatal accident than at home. This is accounted for by the fact that the average duration of each flight overseas was longer than at home. From the material available, it is possible to say that for each of the officers killed during the year in flying accidents (other than R.38) over 4000 hours were flown.

Propeller accidents, accidents in starting motors, motor accidents other than those caused by starting motors, wounds in action, accidental gunshot wounds, other accidents on duty, accidents due to athletics, other accidents off duty, and accidents on leave, are dealt with in detail in the report. From consideration of the material available of accidents caused by starting motors, it appears that three types of cause may be distinguished: 1. By far the commonest, due to the direct impact of the starting handle on the hand at the moment of back-fire, nearly always resulting in Colles' fracture or sprained wrist. 2. Those due to the handle swinging round after the back-fire causing injury, usually of the arm above the wrist. The fracture of the radius or ulna, apart from Colles' fracture, were nearly all caused in this way. Depending on the size of the starting handle and its height from the ground, head and face and lower extremity injuries may more rarely result. 3. A more uncommon type of case occasionally occurs, owing to the starting handle throwing the operator against the radiator or the mud guards of the vehicle.

Sandfly Fever.

Very valuable research work on sandfly fever was carried out by R.A.F. bacteriologists at Malta during the year. This work resulted in the discovery of a spirochæte having morphological characters very similar to the *Leptospira icterohæmorrhagiae* being isolated from cases of sandfly fever. The work is briefly described in the report and further research is still continuing. Apart from Malta, sandfly fever was prevalent in Iraq and India, and in a lesser degree in Egypt and Palestine. A chart is given showing the monthly case-incidence rates in Iraq

* To be purchased through any bookseller or directly from H.M. Stationery Office at the following addresses: Imperial House, Kingsway, London, W.C.2, and 28, Abingdon-street, London, S.W.1; 37, Peter-street, Manchester; 1, St. Andrew's-crescent, Cardiff; or 120, George-street, Edinburgh. 1923. 5s. net.

during 1920 and 1921. From the chart it appears that there was a marked reduction in the case-rate for sandfly fever. But it is impossible to say how much the lowered case-incidence was due to the prophylactic measures taken, as, judging from the experience of the past few years, it would appear that the severity of sandfly fever outbreaks in Iraq vary markedly from year to year.

Malaria and dysentery are dealt with in detail, as in the 1920 report, primary cases being distinguished from other cases.

The Central Medical Board.

The functions and work of the Central Medical Board form a separate chapter. From the table of accepted pilots, it appears that the physical standard of new officer personnel is fully up to the existing standards as determined by war-time conditions. Tables are also given which show the physical efficiency of serving officers. The tables bear out the impression previously held that flying, in addition to being associated with a high degree of physical fitness, is helped by youth and a certain degree of body bulk.

The principal points in relation to hygiene and sanitation form a separate section.

The Nosological Tables.

In the report for 1920 a detailed nosological table was included showing case, death, and invaliding rates for each overseas area, as well as for the United Kingdom and for the total force. In the report for 1921, the diseases have been grouped together under certain main headings, and in addition, all overseas areas have been grouped together in the main nosological table. A more detailed table is given for the more common diseases, and in this table each overseas area is dealt with separately. The effect of this method of presentation is that although the nosological tables cover the same number of pages as in the previous report, the matter on each page of the table is much reduced. This possibly accounts for the fact that the price of the publication is 5s. as compared with 6s. for the previous issue. This reduction, though slight, is satisfactory.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

Proposed Antituberculosis Legislation.

As a result of the enormous increase of tuberculosis during and after the war, the Government has been induced to take more energetic measures against the disease. Among the provisions of a new Bill lately introduced into Parliament are the following: Every case of infectious tuberculosis of lungs or larynx must be notified to the district medical officer within a week of discovery and within 24 hours of death, either by the head of the family or by the medical attendant, or, in the case of hospital patients, by the hospital officials. Notification of change of a patient's residence is also required: where a dispensary station (*Fürsorgestelle*) exists the medical officer must pass the case to that institution for further care, and elsewhere the medical officer, after consultation with the practitioner in charge of the case, must take what steps are necessary—e.g., instruction of the patient and of the family as to danger of infection and as to prevention, especially in relation to the protection of children. Special arrangements will be made against the spread of the disease by teachers, waiters, and all persons engaged in the handling of food. Where no proper attendance is available, the patient may be transferred to a hospital or sanatorium. Private laboratories must notify to the district medical officer every case where tubercle bacilli are found in the sputum. On request of a practitioner or medical officer a local authority must undertake disinfection of a patient's rooms and property; when the expenses of disinfection would

be greater than the value of the things the medical officer may order the latter to be burnt. Expenses of disinfection are to be recovered from public funds if the patient and his family cannot pay them. People omitting notification, or using patients' rooms before disinfection, are to be fined up to 150,000 marks. One difficulty in the way of administration of the Bill is the lack of an exact definition of "infectious" tuberculosis. If the presence of tubercle bacilli is taken as an index, protection for the patient comes rather late. It must, however, be borne in mind that the Bill leaves the treatment of tuberculous patients to the municipalities, the sick-clubs, and the workmen's insurance organisations, being itself aimed only at prevention of the spread of the disease.

Temperance Movement in Germany.

One of the most striking results of the war was the almost complete disappearance of drunkenness in Germany. During the war alcoholic liquor was not produced except for the fighting forces at the front; the German national beverage, beer, was produced in a form ("Schwachbier") containing only 2 per cent. of alcohol, which was very little appreciated, and was consumed in moderate quantities only. Thus, mental diseases caused by the abuse of intoxicants totally disappeared; many lunatic asylums were practically emptied, and a new asylum in Berlin, which was to be available in the autumn of 1914, was occupied for other purposes. It was hoped that after the war the Government would seize the opportunity permanently to reduce the consumption of spirits, and that, should they be unwilling to make Germany totally "dry," they might at least stop the granting of new licences for the sale of liquors. These hopes were unfortunately unfounded: the production of alcohol is a Government monopoly, and shortly after the end of hostilities the sale of liquors began again, on a larger scale than before. The consequences of this abuse are now obvious even to a superficial observer. Intoxication has become common amongst youths; asylums have again become overcrowded, and the financial distress of many working-class families is aggravated by the drink habit. The Association of Medical Abstinents, under the chairmanship of Prof. Abderhalden, the well-known physiologist of the University of Halle, are canvassing the medical profession to sign a petition against the abuse of alcohol. They propose that the sale of spirits should be forbidden to people under 18 years of age, that all bars and restaurants where alcoholic liquors are sold should be closed at 11 P.M., and that the granting and maintenance of licences should depend in any particular city or district on the result of a local referendum. In certain cities private votes have been taken with remarkable results; for instance, in the central district of Bielefeld, a large industrial town in Westphalia, a privately-arranged referendum resulted in 12,000 persons, out of 14,000 on the list, voting that the city should go entirely "dry."

Foreign Patients in Germany.

The influx of foreigners who have come to this country to take advantage of the depreciation of the currency has roused the Government to reduce as much as possible the granting of visas by German consulates abroad. Many Germans cannot find proper housing accommodation, whilst foreigners frequently have very little trouble in procuring well-equipped homes. The thousands of families expelled by the French from the Rhine and Ruhr districts must, of course, be provided with homes: the supply of milk and other food has again become almost as scarce as during the war—an evil aggravated by the number of foreign residents. The measures adopted by the Government, together with the temporary improvement of the exchange, has already reduced the number of foreigners. The medical profession in Germany is interested in this state of affairs, for visas are refused to foreigners who wish to consult German specialists. Prof. Kraus, president of the

Berlin Medical Society, has collected a number of cases where such refusal has resulted in disadvantage to German medical men, sanatoriums, and spas. Even when permission is granted to a foreigner to enter Germany, a time limit is set, and prolongation of the visit is made dependent not on the opinion of the medical attendant, but on a certificate from a district medical officer who cannot, of course, judge a case on its merits. Prof. Kraus has extracted from the Foreign Office a promise that the granting of visas to foreigners coming to Germany for health reasons shall in future be facilitated.

Mercury Poisoning.

A unique case of poisoning was recently shown by Prof. Umber at a meeting of the Berlin Medical Society. A hospital nurse had tried to commit suicide by an intravenous injection of 2 g. of metallic mercury. The first three days no symptoms of poisoning occurred, but after that period heavy diarrhoea, tenesmus, stomatitis, and oppression ensued. At the site of injection an abscess had formed, which on incision discharged metallic mercury and pus. The general symptoms gradually disappeared, but eight weeks later the abscess was again incised, and the symptoms reappeared, once more to disappear completely without leaving any trace. Apart from trifling vasomotor troubles and slight emphysema, nothing abnormal was observed for about half a year after the poisoning. The most remarkable feature of the case was the radiogram shown to the society. Both lungs, especially the right middle and inferior lobes, showed enormous masses of mercury emboli which on the plate appeared as intensely black spots corresponding with the net of the pulmonary arteries; a great lake of mercury was visible within the right ventricle of the heart. Prof. Umber concluded from this case that the collateral circulation of the lungs must be excellent, because the general circulation did not suffer from obstruction of the pulmonary arteries by the emboli; further, he concluded that metallic mercury must be comparatively harmless in relation to the human organism, whereas the application of mercury in the form of ointment or oil leads frequently to grave and sometimes fatal consequences.

Public Health Services.

ALLEGED DISSATISFACTION OF INSURED PERSONS: EXPERIENCE OF KENT INSURANCE COMMITTEE.

IN view of the statements made in the daily press as to the alleged general dissatisfaction of insured persons with the treatment they receive from panel doctors, the following facts extracted from the records of the Kent Insurance Committee have been brought to our notice by Dr. J. J. Day, chairman of the Kent Local Medical and Panel Committees.

From January, 1913, to Jan. 1st, 1923, 149 complaints were received and investigated by the committee. Dr. Day investigated completely the complaints received from January, 1919, to January, 1923. These number 71 in all. Of these, six were brought by doctors against insured persons. One was found to be substantiated; two were found not substantiated; three were dismissed as frivolous. The remaining 65 complaints were made against doctors. Fourteen of these dealt with cases of irregular issue of certificates and were not concerned with questions of treatment in any way; 11 were found to be substantiated; two were found not substantiated; one was not proceeded with. Eleven were cases of charging insured persons for treatment to which they were entitled: seven of these were found to be substantiated; four were found not substantiated. Forty cases involved charges of alleged unsatisfactory treatment: 16 were found to be substantiated; 17 were found not substantiated (in one case the doctor was censured); two were dismissed as frivolous; two were withdrawn; two were not proceeded with; one was found "not proven." Taking the last two groups together (although in the first 11 cases the question of treatment

hardly entered), out of 51 complaints, 47 came up for investigation and 23 of these were found to be proved against the doctors involved.

In 1922 there were 13 complaints against doctors, five of which were substantiated and eight unsubstantiated. The total number of persons on the lists of the doctors involved was 18,920—5438 in the substantiated and 13,482 in the unsubstantiated cases. The total number on doctors' lists in Kent for the year was 300,098. This shows an average of one complaint among each 23,084 insured persons. The average over the four years 1919-22 was one complaint among each 23,753 insured persons. During each year there was an average of over 400 doctors on the panel.

In 1919 611 insured persons changed their doctor, while 244,680 were content to remain under their original doctor. In 1920 the numbers were 743 who changed and 271,820 who did not. In 1921 850 changed and 297,591 did not. In 1922 1433 changed, while 298,665 did not.

During the four years 1919-22, 375 doctors applied to have patients removed from their lists.

Dr. Day submits these facts without comment or argument, leaving his readers to judge for themselves the state of affairs in Kent.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

Lowestoft.

THE Town Council of Lowestoft have decided to employ a full-time medical officer of health and school medical officer for the borough and port sanitary district, at a salary of £700 per annum. The acting medical officer of health, Dr. W. Hotson Palmer, has just issued his annual report for 1922. The total number of births in the year was 980, and of deaths 560. The birth-rate of 22.0 shows a decrease as compared with 25.6 for the previous year. The gross death-rate was 12.6, and the infantile mortality 72 per 1000, both slightly higher than in 1921. There was an epidemic of scarlet fever of a mild type during the year, and many cases of the disease probably went unrecognised, and so spread the infection. The total number of cases of diphtheria notified was 72; there were 11 deaths. In all the fatal cases occurring in the sanatorium diphtheria had been present five days or more before admission, and Dr. Palmer considers that most or all of these lives would have been saved had attention been called to the disease earlier. Chicken-pox was made notifiable on Dec. 22nd, 1922, and 32 cases were notified before the end of the year. There were 46 deaths due to bronchitis, 43 to cancer, 43 to organic heart disease, 31 to pneumonia, 14 violent deaths, and 5 suicides. An extensive sewerage scheme embracing the rural and Oulton Broad areas of the borough has been inaugurated, is now practically complete, and should be in working order in about six months. When completed this will enable the sanitary authority to deal effectively with the objectionable privy-middens and cesspools at present existing in those previously undrained areas. One hundred and thirty-four new houses were erected, or were in course of erection, during the year.

NORFOLK AND NORWICH EYE INFIRMARY.—At the annual meeting of the governors recently held the committee stated that satisfactory progress had continued during 1922; the in-patients numbered 244, and the out-patients 1631, with a total attendance of 5613. The income for the year from all sources was £2567, and the expenditure £1995, leaving a balance in hand of £572. The almoner reported that the system of making a small charge to patients had continued to work satisfactorily. The amount paid by in-patients was £122, and by out-patients £133. Last year was a notable one in the history of this institution. The infirmary was founded on July 11th, 1822, and on July 11th, 1922, its centenary was celebrated. The question of amalgamation of the Eye Infirmary with the Norfolk and Norwich Hospital has been finally decided on, subject to the separate identity of the Eye Infirmary being retained, and a subcommittee representative of both institutions has been appointed to prepare a working scheme, to be submitted to the governors of both hospitals for their approval.

"Audi alteram partem."

INSURANCE PRACTICE.

A LETTER FROM A COUNTRY PRACTITIONER.

To the Editor of THE LANCET.

SIR,—I have been trying to think out the advantages of panel over the old club practice and can only find one. It is a very obvious one—increased remuneration. On the old club system we only got 4s. per member per year. This, of course, did not anything like pay a doctor for his work; but the fault originated among ourselves. When there was a vacancy for a club medical officer it was always keenly competed for. I think this was at first due to the fact that the doctor considered that by taking the members at a nominal figure he would assuredly get the majority of the wives and families. Later, at the request of the Guardians, during the hard years when the labourers earned at the most 12s. a week, and in order to lessen the parish work, the doctors formed what are still known as "surgery clubs" for the wives and children of club members. The money—1s. per quarter for adults and 6d. for children under 15—was collected every quarter from the village public-houses. This made the post of medical officer to a club much less valuable—in fact, destroyed its value altogether. Why medical men still competed for these posts it is difficult to say. Probably it was thought that to have 1000 surgery club members, although not paying in itself, would still bring grist to the mill.

I have said that the increased remuneration is the only point in favour of the panel system. But although to my mind there are many points against the new system, the advantage of increased remuneration overshadows them all. And yet in the old days a young fellow, straight from hospital without wife or family, in starting practice on his own or as an assistant, could enjoy the work and the experience, for it always does one good to do something for nothing. When I started 22 years ago I loved it. I used occasionally to attend the Lodge meetings, having gone through the ordinary ceremony of initiation, and I remember to this day the spirit of real fraternity prevailing there. Bro. So and So was in trouble or needed a truss of other appliance and extra remuneration was always allowed. The medical officer was looked up to with respect. He was asked to preside at their dinners and functions. When complaints arose, as they sometimes did, a deputation waited at the surgery to put the case and invariably went away satisfied. Of course all this is altered. We dealt with brothers then, we deal with material now.

When State insurance came in we studied the numerous rules and regulations and got a fair grip of them at the start. But the panel pigeon-hole soon became choked with new rules and amendments. One now found oneself under the letter of the law. It was easy to see that the regulations were framed for the town practitioner, that some of them were next to impossible in the country. Any doctor with a heart wants to infringe these rules. Example: A woman comes in; lives at village five miles away; asks for a certificate for a husband with influenza. Your journeys are all the other way to-day. Medicine and advice will do until to-morrow, but someone must come five miles for the certificate. Next case: Man comes in looking really ill, also living at a distance. "Doctor will you give me a certificate. I have not been to work for three days, but hoped I should throw it off in a day or two. Will you date it back to Monday for me." One has to reply, "No, go home and go to bed, but I cannot date certificates back." In the old days, when the doctor was a trusted person, it was left to his discretion. For patients who live within a mile from the chemist the bog of expensive prescribing hangs over our heads although we supply

what we can from our own dispensaries. Casualties come in and in the urgency of the moment we use up all our own dressings. If afterwards I prescribe 1 lb. of cotton-wool and three or four bandages to make up for the number missed I am taken to task for expensive prescribing.

We get word that the Government referee is coming down for an annual inspection. Shall we write and ask him to lunch? No bribery, play the game! Agreeably surprised to find he is flesh and blood. He examines the "record cards" which, by the way, are good as clinical records even if no good for statistics; but there are times when the country panel doctor is too tired to care whether he puts down his own good marks or not. Referee makes a great point of the fact that you have not filled in the left-hand bottom corner of the card where it runs "State whether married (M) single (S) or widowed (W)." This you understand is most important for statistics. He looks in your bottle shop and seems surprised: "My dear fellow, how much do you spend on drugs?—What! £250? Absurd! When I was in practice I did it on £40."

Anyhow, thank God I am a country practitioner! It is the most humane of occupations. One learns to sympathise with men in their sorrows, yea even in their sins, knowing that every man has a hard fight against many odds. One learns how to be happy and high-minded amid the meaner drudgeries of life. No voice of distress reaches our ears in vain. But the one phobia from which the country practitioner suffers is that of becoming out of date. I had the fear when I first started in practice. A few years back I spent my three weeks' holiday acting as senior house surgeon at my own hospital as a preventive, but still the phobia. How the Ministry of Health might help us here. They must have their statistics to feed the wolfish appetite of the public, but let us have in addition a body of real useful consultation referees. Let one come to our district every quarter and stay a week. We always have a dozen obscure cases which we cannot diagnose without reservation, or whom we want to help. It is the undiagnosed case that saps the life of the conscientious practitioner. Let the consultant's duty be that of affording post-graduate instruction in a friendly way to the doctor, and a senior country practitioner's life will again become worth living.

I am, Sir, yours faithfully,

RUSTICUS.

April 13th, 1923.

* * We comment upon this suggestive letter in a leading article.—ED. L.

SERUM DOSAGE IN DIPHTHERIA.

To the Editor of THE LANCET.

SIR,—Dr. C. B. Ker pointed out in your issue of March 31st that small doses of antitoxin are often efficacious and 8000 units—as recommended by the Ministry of Health—often unnecessary. The limited experience of a general practitioner may be of interest; he often sees the case early, the fever expert late. During 5½ years I have seen 126 cases of diphtheria, fortunately most of them early as the public are becoming educated to the horrors of the disease. It had been my practice to give 2000 units in early cases till the gratuitous distribution, since when I have given 4000. I always carry an antitoxin outfit in my car (the empty cartons make excellent bulb-carriers!), so that not more than five minutes need elapse between diagnosis and injection. Of 120 cases that recovered the only complications were tracheotomy in one case (seen late) and a slight nasal voice for a few days in another. When I return from a holiday, however, it is quite common to see three or four cases of palatal paralysis who have had a "sore-throat" during my absence, no antitoxin having been given. There are also cases seen for the first time with cardiac symptoms and a history of sore-throat a week or two previous.

I often wonder how many myocardial conditions are due to latent untreated diphtheria. I have had

six deaths—a terrible and largely avoidable mortality of nearly 5 per cent.; thus, of four of these, in two I was not sent for till the third day, in one the fifth day, and in one the sixth day! Three of them died of cardiac paralysis and one of oesophageal paralysis. Of the other two deaths—in one the initial diagnosis was ? scarlet fever, in the other septic throat, with consequent delay. These are but a small number of cases, yet they are typical and a larger number would show, I hope, improved results as the wisdom of the public and the doctor grows. Dr. F. Thomson speaks of the inability of the inexperienced man to distinguish a mild from a severe case. Is it not, rather, as Dr. Ker says, the promptitude with which antitoxin is given that matters? All the cases I see early seem mild enough, whereas all the fatal cases were either seen or treated late. One lesser point—what percentage of cases develop an antitoxin rash? I have seen only two, whereas the percentage is given in a well-read "Skin" book as 33.

I am, Sir, yours faithfully.

Aberdare, April 11th, 1923.

AMBROSE W. OWEN.

BREAKDOWNS AND LOWERED IMMUNITY.

To the Editor of THE LANCET.

SIR,—The question must often suggest itself why one person in a hundred or a thousand dies suddenly of influenza, septicaemia, pneumonia, &c. Young and strong men and women die of influenza, and, as in a recent well-known case, an apparently healthy man in the prime of life, after some months of anxious work in a warm climate dies as the result of a mosquito bite. In such cases the risks of invasion by pathogenic organisms are not extraordinary. The individual may have been exposed to exactly the same risks many times before without ill-effect. Such facts seem to warrant the hypothesis that the normal resistance of the tissues may be suddenly lowered or altogether broken down without obvious signs of ill-health.

This letter is intended simply as a note of interrogation. Can our experts in immunity say how far it is now possible to detect and measure this loss of resistance to those fatal maladies? The new work on diphtheria raises one's hopes. Granted such knowledge it might be comparatively easy to go a step farther, and, by specific or non-specific means, restore the normal resistance of the tissues.

I am, Sir, yours faithfully.

London, April 12th, 1923.

R. FORTESCUE FOX.

HOFFMANN'S BACILLUS AND ACUTE TONSILLITIS.

To the Editor of THE LANCET.

SIR,—In an annotation entitled Recent Work on the Schick Test, which appeared in THE LANCET of April 7th, dealing with the report by Dr. S. F. Dudley to the Medical Research Council, this author seems to have assumed that Hoffmann's bacillus is non-pathogenic. I feel that this assumption cannot pass unchallenged and for the following reason.

In 1918, while in a military hospital in England, two men were admitted to the wards suffering from acute tonsillitis. The appearance of the throat in each case was suggestive of diphtheria, but the exudate was not typical. Swabs were taken and subjected to careful bacteriological examination, with negative results for *B. diphtheriae* but positive for *B. Hoffmanni*. On the result of the bacteriological findings no serum was given, but local applications, and general medication prescribed. As no improvement was taking place swabs were again examined with the same result. The patients both became very toxic, and developed oedema, with scanty output of urine. The urine, which was clear on admission, was re-examined in both cases, and abundant albumin, blood, and casts were found. Swabs were examined a third time and

still the same result. Both patients ultimately died from extreme toxæmia and practically anuria. In these cases treatment had been in the form of local applications and general medication throughout, and no serum of any kind had been administered.

Following on these cases four other patients were admitted with acute tonsillitis, and the early clinical condition was identical with the cases above recorded, and swabs were taken with the same bacteriological results—viz., positive for *B. Hoffmanni*, and negative for *B. diphtheriae*. I suggested to the medical officers in charge of the cases to try anti-diphtheritic serum, as previous treatment had been valueless, and 6000 units of serum were given subcutaneously in the lax tissues of the abdominal wall. The result justified the more or less speculative form of treatment, for almost immediate improvement took place in the clinical condition of the patients, and the throat cleared up in two to three days. Convalescence was slow but uneventful. None of these cases developed any marked toxæmia or kidney symptoms, as proved by systematic examination of the urine.

From this experience I have continued to consider *B. Hoffmanni* as distinctly pathogenic, and in its local and general toxic effects to resemble very closely those produced by *B. diphtheriae*. In practice I have encountered six cases of acute tonsillitis where the clinical aspect has suggested an infection by *B. diphtheriae* and where *B. Hoffmanni* has been found to be the infecting agent. In these cases I have given doses of anti-diphtheritic serum varying from 4000 to 8000 units, and the results obtained seem to justify this procedure, for the throats clear up rapidly without complications.—I am, Sir, yours faithfully,

DAVID SMITH, M.D., F.R.F.P. & S. Glasg.,

Physician to Out-patients, Royal Infirmary, Glasgow.
April 10th, 1923.

A CHLOROFORM TRAGEDY: THE QUESTION OF RESPONSIBILITY.

To the Editor of THE LANCET.

SIR,—According to the press reports of a recent inquest a patient about to undergo an operation lost her life owing to the anaesthetist using a chloroform inhaler the tubes of which had been wrongly connected. It would appear from the report that the woman doctor succeeded in shifting the responsibility for this on to the theatre sister, for the jury added a rider to their verdict that in future the theatre sister should be responsible for all apparatus and instruments in the operation theatre. This rider does not define the extent of responsibility, and, strictly speaking, the words would appear to mean "responsible for safe custody," but from the context it is clear that the jury meant to imply that the theatre sister should be responsible for the proper putting together and proper working of the apparatus. If this be so, it is not common sense, and, I venture to suggest, is not good law. As to the action of the doctor in shielding herself by blaming inferentially her subordinate, I express no opinion, but the rider of the jury should not be allowed to pass unchallenged. The theatre sister's duty is to keep the various instruments and apparatus clean and in proper order. During the operation she is under the direction of the surgeon, and so she can hardly be held responsible for the way in which the various instruments are used. Clearly, it is the anaesthetist's duty to see that the apparatus is in proper order before it is used. The position is somewhat analogous to that which arises when at an operation a swab is left in the abdominal cavity. The responsibility is the surgeon's. He may delegate the checking of the swabs to the sister, but the responsibility still remains his. "Qui facit per alium, facit per se." A surgeon, like any other mortal, may make mistakes, but any attempt to put the blame for errors of this kind on to the nurse is not only unfair but unjust, and should not receive either moral or legal sanction.

I am, Sir, yours faithfully.

HERBERT J. PATERSON.

London, W., April 14th, 1923.

THE LIFE-HISTORY OF THE TAPEWORM, *HYMENOLEPIS NANA*.

To the Editor of THE LANCET.

SIR.—The life-history of the dwarf tapeworm, *Hymenolepis nana*, has been, for many years, a subject of medical interest and discussion, the importance of which arises from the fact that it is regarded as one of the commonest tapeworms of man in certain parts of the world. The fact that a morphologically indistinguishable tapeworm is known to occur in rats adds complexity to the matter. For long, indeed, it was the custom to consider the two as in every respect identical, but certain experimental results have served to cast doubt on this assumption.

The problem, apparently simple in essence, presents unexpected difficulties, and to me there seems the necessity that more than usual care should be exercised in giving expression to any opinion dealing with it. On that account I venture to correct a slightly misleading statement occurring in a recent issue of the *Tropical Diseases Bulletin* (vol. xx., No. 2) to the effect that Nicoll and Minchin claim to have obtained cysticercoids of this species in fleas. As one of the writers to whom this "claim" is attributed, I may be allowed to state that no claim was intended and there is nothing in the published report (Proc. Zool. Soc., 1911) to suggest such. The intricacy of the subject was perfectly familiar to me at the time and, moreover, my friend, the late Prof. Minchin, was, I take it, too well acquainted with the pitfalls of experimental research to associate his name with the publication of an assertion the correctness of which had not been satisfactorily demonstrated.

I may note that, following the publication of our communication to the Zoological Society, further investigations were carried out but with no result sufficiently unequivocal to justify definite statement. The matter has since been taken up by other workers, but it is unnecessary here to enter comment on their results.

I am, Sir, yours faithfully,

London, S.W., April 12th, 1923.

WM. NICOLL.

THE ADMINISTRATION OF ANTI-DIPHThERIC SERUM.

To the Editor of THE LANCET.

SIR.—The annotation in your issue of April 7th on practical points in the administration of anti-diphtheritic serum seems to me an unfortunate one, for while very properly calling attention to the want of appreciation on the part of the general practitioner of the importance of early injection of antitoxin, it also raises a sort of academic red herring by asking for records of experience of its intravenous administration. I have had considerable experience of intravenous injection, but I am not going to write of it in conjunction with the necessity for the early and adequate administration of antitoxin. The one is of small importance, whereas the other is a matter of life and death.

In May, 1921, I had occasion to write you drawing attention to the delay in the treatment of diphtheria, and which I then said was greatly attributable to awaiting the result of bacteriological examination. That fact, and to a lesser extent the delay of parents seeking medical advice, are the cause of an appalling number of deaths. I think there has been somewhat less waiting for the bacteriological examination of late, and some medical officers of health post notices in public places urging parents to have all sore-throats seen by medical men. I wonder how many medical officers of health do this?

Dr. B. A. Peters, in his letter in your issue of April 14th, tells us that the M.O.H. in his area circulates all practitioners from time to time advising the dosage which is based on the type of the disease prevalent at the time, and he adds that he thinks this a wiser plan than attempting to set up standards for

the whole country. As far as I am aware, nothing in the past prevented this being done, but I wonder how many did it? It is possible, I suppose, that some medical officers of health are not very well versed in the dosage of diphtheria antitoxin, and I do not think very many would claim to be; indeed, I have been told by several medical practitioners that they were unable to procure from the M.O.H. more than 4000 units for a patient. Dr. Peters says the Ministry of Health advocates too low dosage to arrest the type of disease in his area. This is not so! The wording of the memorandum is:—

"Experience has shown that for the purposes of treatment it is seldom safe practice to rely on any dose which is less than 8000 units, whatever the age of the patient may be. The magnitude of the initial dose and the occasions on which subsequent doses are given must be determined by close observation of the case and it is impossible to lay down a stereotyped procedure. As an indication it may be stated, especially from the experience of Metropolitan Asylums Board hospitals, that when in a case seen early in the attack an initial dose of 8000 units (16,000 or more if the case is severe). . . ."

As I read this, the M.O.H. can advocate any dose to meet any variation in the type of the disease in his district so long as he does not advocate less than 8000 units, and I do not take it that Dr. Peters is objecting to this minimum dose.

What appears to me sad about Dr. Peters's letter, however, is his telling us that of the last 80 fatal cases in his hospital 19 received doses of from 2000 to 10,000 units within the first 48 hours while awaiting bacteriological confirmation before admission, but that these amounts were insufficient to prevent death. I imagine most of them would have recovered if all had received an initial dose of 8000 units or more, as advised by the Ministry of Health; and at all events either wrong advice as to dosage was given or the medical practitioners did not take it.

I am, Sir, yours faithfully,

FREDERIC THOMSON.

North-Eastern Hospital, South Tottenham,

ALCOHOL AND INSANITY.

To the Editor of THE LANCET.

SIR.—If anyone chooses to assert, without other evidence than is provided by his own inner consciousness, that alcoholism (or tea-drinking, or smoking, or newspaper reading) is the chief cause of insanity, then, according to Dr. S. Wyard, the assertion is to be accepted until it is disproved, the burden of disproof resting on the sceptic. It is not enough to show that the elimination of an alleged chief cause has failed to bring about any decrease of insanity. That is, it seems, quite irrelevant unless it is also proved that none of the other innumerable antecedent conditions, to which causal influence may conceivably be imputed, have increased in proportion to the diminution of the supposed chief factor. If that is Dr. Wyard's argument, discussion can hardly be profitable.

I am, Sir, yours faithfully,

W. C. SULLIVAN.

Broadmoor, Crowthorne, Berks, April 15th, 1923.

WOMEN IN THE POST OFFICE MEDICAL DEPARTMENT.

To the Editor of THE LANCET.

SIR.—I shall be obliged if you will allow me briefly to reply to the letters on the above subject in your issue of March 17th.

Lady Barrett does not point out any misleading statement in my former letter. An expression of opinion is not a misleading statement, and I have given examples of men having to accept lower salaries in consequence of the employment of women in the above department.

I have nowhere suggested that any particular class of qualified women was not available; but that it was not necessary. In the P.O. medical service all the women and the men are under the chief and second M.O.'s. The women's branch and the assistant M.O.'s (men) branch are separate and distinct practices. Though a woman with 30 years' service may be receiving a larger salary than a man assistant in his early service she has nothing whatever to do with his work, administratively. On the other hand, in the absence of the chief or second M.O.'s the men assistants move up, and become acting chief and second M.O.'s; thus the women M.O.'s come under their supervision. A woman is never called upon to act as chief or second M.O. The first assistant M.O. (men) can count upon being acting C.M.O. for short periods during the year, and acting second M.O. for at least four months. The second assistant M.O. will act as second M.O. for shorter periods. For this work they receive no extra pay whatever beyond the slight difference on scale between the assistant M.O.'s male and female. If the Federation does not dispute the justice of demanding a higher standard of qualification and experience for the higher posts why deny the right of the men, who possess these essentials, to a slightly higher rate of pay than a woman who never performs these duties? How can it be maintained that the responsibilities of the men and women M.O.'s are equal and that they do exactly similar work? This is one instance only to the contrary.

In my last letter I dealt with the manifesto wherein was the statement that one woman—a candidate for an appointment in 1911—withdrawed her application when she was informed by some unknown person that she would not receive the same rate of pay as the men received for similar work. By March 17th the one has budded into several. Apparently these women were satisfied with the particulars of the appointment supplied to them, and before anyone can discuss the matter we should be informed how the names and addresses of the applicants became available, and the nature of the communication they received. Possibly the information was inaccurate and they withdrew under misapprehension.

One word about these traditional loyalties of the medical profession and standing together sentiments. Remembering that the women have nothing whatever to do with the work of the men, and turning again to the manifesto, we find that in 1920 the female M.O. constituted herself a court of inquiry into the capabilities of the men. She called the late C.M.O. as a witness, then broadcasted with the aid of the Federation her comparison of the professional merits of the men and women. The men had no say in the matter. Is this a woman's way of showing traditional loyalty to her department and colleagues?

Medica states that the first woman appointed was placed third from the top, but neglects to say this was the bottom position on the day staff. She should read her letters more carefully if she wishes your readers to think I have stated that woman's work is valueless. The retirement—I in 41 years—was taken from the manifesto, and I said nothing about past holders of office, and plainly referred to present conditions. There are no such titles as "senior" or "principal" female M.O.'s in the P.O., and the fact that during the past 40 years the female M.O. has performed one solitary journey into the country, when accompanied by one of her superior officers (men), proves my statement that whilst men assistant M.O.'s frequently do this kind of work, the women assistants never do it—another illustration of the fact that the women assistants do not perform "exactly similar work" to the men. The appointment in 1889 was under no different conditions to those preceding it.

That the P.O. is justified in expecting a higher qualification and experience from men than women is obvious. I am, Sir, yours faithfully,

April 9th, 1923.

CLERICUS.

The Services.

ROYAL ARMY MEDICAL CORPS: EXAMINATION FOR COMMISSIONS.

AN examination for not less than 20 commissions in the R.A.M.C. will be held on August 1st. Applications to compete should be made to the Secretary, War Office, not later than July 20th. The presence of candidates will be required in London from July 30th. Prospective candidates can obtain a full statement of the duties and emoluments of the service on written application to the Secretary (A.M.D. 1), War Office, Whitehall, S.W. 1.

ROYAL NAVAL MEDICAL SERVICE.

R. W. Higgins to be Surg. Lieut.

ROYAL NAVAL VOLUNTEER RESERVE.

G. F. S. Parker (late temp. Surg. on probation) to be Surg. Sub-Lieut.

ROYAL ARMY MEDICAL CORPS.

Maj. R. C. Wilson to be Lt.-Col., vice Lt.-Col. and Bt. Col. J. S. Gallie, promoted.

Cpts. G. A. E. Argo (who is granted the rank of Maj.) and S. S. Crosse retire, receiving a gratuity.

Cpts. R. Fisher and H. H. Brown to be Maj.

Capt. W. J. Dowling relinquishes his commn. on account of ill-health contracted on active service and retains the rank of Capt.

Capt. M. S. Double relinquishes his commn. and is granted the rank of Maj.

General Hospitals: The undermentioned officers having attained the age limit are retired and retain their rank except where otherwise stated: Lt.-Cols. (Bt. Col.) W. J. Maurice, W. T. Brooks, W. Collier, and R. H. A. White-locke; Maj. Sir G. S. Abram, A. P. Dodds-Parker (granted the rank of Lt.-Col.), L. M. Guilding, E. Mallam, J. A. P. Price, W. A. P. Waters, J. C. R. Freeborn, W. J. Turrell, R. G. P. Lansdown (granted the rank of Lt.-Col.), and F. H. Edgeworth; Cpts. N. B. Clowes, C. A. Coventon, W. Duigan, G. H. R. Holden, G. F. Murrell, W. B. Prowse, R. Ritson (granted the rank of Maj.), R. H. Sankey, A. L. Ormerod, J. F. Robinson, R. G. Lynam, F. Clarke, E. W. S. Rowland, T. B. Marshall, A. G. Kewley (granted the rank of Maj.), F. G. Gardner, J. Gardiner, E. Morton, and J. Henderson (granted the rank of Maj.).

Cpts. W. A. Campbell (granted the rank of Maj.) and A. Mitchell (retaining the rank of Capt.) relinquish their commns.

MILITIA.

Capt. and Bt. Maj. L. W. O. Taylor to be Maj.

TERRITORIAL ARMY.

Supernumerary for Service with the O.T.C.: Capt. C. J. A. Woodside to be Lt. for service with the Medical Unit of the Belfast University Contingent, O.T.C., and relinquishes the rank of Capt.

TERRITORIAL ARMY RESERVE.

Capt. C. A. Pannett, from 3rd Lond. Gen. Hospital, to be Maj.

ROYAL AIR FORCE.

The following Flight-Lts. are transferred to the Reserve Class D.: O. St.L. Campion and M. J. Cahalane.

INDIAN MEDICAL SERVICE.

Lt.-Col. P. Dee to be Col.

Cpts. C. A. Wood, J. A. Sinton, D. FitzG. Murphy, E. E. Doyle, and C. M. Plumptre to be Maj.

Nagendra Narain Majumdar to be Captain on relinquishment of his temp. commn.

Col. A. E. C. Keble, late R.A.M.C., has been appointed a Commander of the Military Division of the Order of the British Empire, and Capt. (Acting Maj.) G. A. F. Argo, R.A.M.C., Capt. (Temp. Maj.) J. M. MacKenzie, R.A.M.C., Capt. (Acting Maj.) M. P. Power, R.A.M.C., and Temp. Capt. J. S. Pinto, I.M.S., to be officers of the Military Division of the same Order for services rendered in the Field with the Waziristan Force.

Obituary.

ARTHUR CARLYLE LATHAM, M.A. OXF. AND
CAMB., M.D. OXF., F.R.C.P. LOND.,
PHYSICIAN TO ST. GEORGE'S HOSPITAL, AND LATE DEAN
OF THE MEDICAL SCHOOL.

WE regret to announce the death of Dr. Arthur Carlyle Latham, physician to St. George's Hospital, which occurred at a nursing home on Friday last, April 13th.

Arthur Latham, born 56 years ago at Cambridge, was the last surviving son of Peter Wallwork Latham, who was for 20 years Downing Professor of Medicine at Cambridge, and whose ninetieth birthday we recently commented upon in THE LANCET. He was educated at Fettes and Balliol College, Oxford, and obtained a first-class in natural science schools, winning also the Radcliffe Travelling Scholarship and being Research Scholar of the Grocers' Company. He completed his medical education at St. George's Hospital, where he was University scholar, afterwards periodically studying at Vienna, Heidelberg, and Berlin, and becoming the translator of Bing's "Pharmacology" and Limbeck's "Pathology of the Blood."

He was promptly elected assistant physician to the hospital and also to the Brompton Hospital for Diseases of the Chest. At St. George's Hospital he soon made his mark both as a teacher and clinician, while he was dean of the medical school at a trying time in the educational history of the hospital. In 1902 he won in open competition the first prize for an essay in connexion with the erection of a sanatorium in England for tuberculosis (King Edward VII. Sanatorium), and the publicity which attended the scheme and the award of prizes considerably enhanced his reputation as an authority on tuberculosis with the lay world, while it was already high among his colleagues. It was an unfortunate circumstance that he should, not long afterwards, have severed abruptly his association with the Brompton Hospital, but he had become connected with the Mount Vernon Hospital for Diseases of the Chest, and felt that in the general wards of St. George's, at his special hospital, and in his private practice he would never have any lack of clinical material. None the less Latham deprived himself of great chances of professional coöperation in matters in which he was deeply interested, and it was always felt by his friends that he had made a tactical error. Probably, however, his practice did not suffer thereby, for he undoubtedly became a general consultant of great repute, whose advice was specially sought in tuberculosis and pulmonary and cardiac disease.

Apart from his distinction as a clinician he earned a high reputation as an organiser, and when in 1907 practically all the metropolitan medical societies, save the Medical Society of London, were combined to constitute the Royal Society of Medicine, Latham, who had given endless time and trouble to assist Sir William Church and Sir John MacAlister in bringing about the movement, was elected one of the first honorary secretaries, Mr. H. S. Pendlebury being the other. This post he held for five years, and all those who worked with him can testify to his unsparing and self-sacrificing zeal, but outside his circle of collaborators little was known of the part that he played. And it may here be added that throughout his life Latham's object seemed to be to conceal his forethought for others, his high professional standards, and his eagerness to advance alike the cause of scientific medicine and the prospects of those who live by our calling. To hear him talk was to gather the impression that he was a cold and cynical man; to follow his actions was to find him revealed as the exact opposite.

From a colleague who was particularly associated with him in connexion with the treatment of tuberculosis we have received the following estimate of Latham as a physician: "Arthur Latham struck all

who came into professional connexion with him as possessing to a highly developed degree the instincts of the physician. He owed remarkable success in diagnosis, alike to his close and learned observation of pathological phenomena and to his broad-minded attitude towards life, which enabled him to make due allowances for the patient's general constitution, methods of living, and psychical make-up. It was this range of observation which used to surprise his colleagues when its results appeared in the form of instinctive surmises. His help was largely sought from an early point in his career as a consulting physician, but he had not the temperament to make himself personally popular either with practitioners or with patients. He was brief, abrupt, and dogmatic; he laid down the appropriate course to be pursued in terms which were not always agreeable to others, and it is known that some of these resented their inability to produce upon him the impression which they considered was the right one. No desire to be agreeable to any patient would allow Latham to permit a latitude which he did not consider was in the interest of the subject. His insistence upon a strict interpretation of the advice which he tendered brought occasional antagonism to him from relatives of his patients, and the readiness in such circumstances with which he appeared to welcome a difference of opinion gave a wrong view. He appeared as an arrogant man, whereas he was thoughtful and generous in directions where he felt that these virtues should be exercised. He was very impatient with all who tried to deceive him, and too intellectually capable not to resent the attitude of those who deceived themselves."

Latham was not a prolific writer, and confessed to being without the necessary patience to bring what he wrote up to his ideals. But to the "System of Treatment," which he edited with Sir Crisp English, he contributed certain sections which illustrated both the range and exactness of his knowledge; he was the author of a convenient "Dictionary of Medical Treatment" intended for junior practitioners and students, with whose dilemmas he was always in sympathy; and his book "The Early Diagnosis and Modern Treatment of Pulmonary Consumption" reached a fourth edition. On the infrequent occasions of contribution to debates or medical journals, what he had to say was always worth saying, and his last paper in our columns, upon bronchial asthma, aroused much interest in the connexion between the disorder and protein sensitisation. He was an admirable public speaker, as all will recall who heard his various addresses on the proper relation of medicine to the public, delivered in connexion with the Federation of Medical and Allied Societies, in whose objects he was deeply interested.

British medicine and the British public have lost much in the person of Arthur Latham.

Dr. LEONARD WILLIAMS, in the following brief appreciation, bears witness to the qualities of his dead friend:—

"To appreciate Arthur Latham's great qualities it was necessary to have known him *dans son intimité*; and into that *intimité* very few were admitted. About 15 years ago circumstances pushed me suddenly beyond the rather forbidding portals, and since that time I had known him very intimately, in many ways more intimately probably than any one else. There has seldom been a man with a more impenetrable mask; seldom, indeed, one whose mask was more worth penetrating. To casual observers, and even to many who were the reverse of casual, he seemed to be the embodiment of clear-headed, far-seeing efficiency—that, and little else. In reality, beneath the polished steel of his orderly intellect, and of his incisive and cynical speech, there lay concealed an emotionalist, with one of the tenderest hearts that ever beat within a human breast. It was seemingly ordained that he should suffer, and suffer horribly, through that very tenderness. It was his lot to see his brothers die early and tragical deaths; the only

two men whom he really loved, Herbert Allingham and John Nachbar, were taken from him; the one dramatically, the other slowly and inevitably. His domestic life was a long-drawn-out pattern of unflinchingly courageous misery. He was greatly gifted. He had one of the acutest constructive brains that I have ever come in contact with, and his destructive criticism was as sound as it was usually merciless. The real distinction of his fine character and great attainments was written on his Napoleonic features; and so, latterly, was his acute and constant physical and mental suffering. The customary gravity of his face would occasionally be relieved by a smile of almost feminine sweetness and beauty, for he loved the lovable in life and had a keen and subtle sense of humour. He has succumbed to a long, painful, and exhausting illness, and, fond as I was of him, and much as I shall miss him, I cannot regret his release. He was a lonely man, who had outlived his ambitions and lost his illusions: may he rest in peace."

THE LATE DR. ALFRED GEORGE SIMMINS: AN APPEAL.

OUR readers may have noticed in THE LANCET of March 31st the coincidence of the death on March 23rd of Temp.-Surg. Lieut. Alfred George Simmins, R.N., and his wife. The double event was due to influenza, and the husband was only 32 years of age, the wife being just his senior. Dr. Simmins was educated at Guy's and Westminster Hospitals, qualified in 1914, and on the outbreak of war gave up a post in the Metropolitan Asylums Board to serve in the Navy. During his period of service he took the degrees of M.B., B.S. Lond. Demobilised in 1919 he acted for a time as medical registrar at Westminster Hospital before succeeding Dr. Croly in general practice at Hornsey. His excellent record was a guarantee of professional success, to which death has put so tragic a term.

We have received the following moving appeal on behalf of the children left orphaned in this pathetic manner: "They leave three little children, for only one of whom—a boy of 6—some provision has been made. No funds are available for the education of the other two, a girl and boy, aged 4 years and 15 months respectively, and they are left penniless orphans. At the time of the catastrophe Simmins was making good, but there was an overdraft at his bank as a result of the purchase of his practice, and he was precluded from the ordinary terms of life insurance by albuminuria, the relic of a previous attack of influenza. Even in these case-hardened days it would be difficult to find a parallel to such a combination of misfortunes, and we are proud to believe that our appeal will evoke a generous response from all branches of the profession. A committee is in process of formation, and several generous donations have already been received."

The appeal is signed by Sir William Hale-White, Sir James Purves-Stewart, Dr. G. F. Still, Dr. Henry C. Semon, and Dr. David Nabarro. Cheques and postal orders should be sent to the Treasurer, Simmins Appeal Fund, and addressed Royal Northern Hospital, Holloway-road, N. 7.

The following contributions have already been received:—

	£	s.	d.
Dr. G. F. Still	50	0	0
Mr. L. E. Barrington-Ward, F.R.C.S.; Mr. H. Tyrrell Gray, F.R.C.S.; Sir William Hale-White; Sir James Purves-Stewart; Dr. Henry C. Semon; Mr. G. E. Waugh, F.R.C.S.	10	10	0
Mr. H. A. T. Fairbank, F.R.C.S.; Dr. F. John Poynton	10	0	0
Dr. Joseph Birt; Dr. R. S. Frew; Sir Alfred D. Fripp; Dr. C. B. Heald; Mr. T. Twistington Higgins, F.R.C.S.; Sir W. Arbuthnot Lane; Dr. David Nabarro; Dr. Wilfred J. Pearson; Dr. Hugh R. Phillips; Dr. Harold Sington (first donation); Dr. Hugh Thursfield	5	5	0

INSULIN AND THE TREATMENT OF DIABETES.

ON Nov. 17th, 1922, and Feb. 21st, 1923,¹ the Medical Research Council published statements explaining the measures which have been taken in this country for studying the production and the properties of insulin, and for promoting its manufacture here upon a commercial scale. The following additional statement can now be made:—

Large-Scale Production.

British-made insulin is now being supplied from two sources—namely, the firm of the British Drug Houses, Ltd., in conjunction for this purpose with Messrs. Allen and Hanburys, and that of Messrs. Burroughs Wellcome and Co. These firms, who undertook the manufacture under agreement with the Medical Research Council, have satisfied all the requirements and tests of the Council for authenticity, standard value, therapeutic efficiency, and sterility of the product sold. It is hoped that these sources of supply will be augmented at an early date by three other firms in different parts of Great Britain who are under similar agreements with the Council. It should be understood that the rapid progress made by these five firms since the end of last November, and the actual achievement of successful and guaranteed supply within a period of little more than four months from the first attempts at large-scale production, have been made in spite of some serious handicaps. The large quantities of alcohol used for extraction brought the manufacture under almost prohibitive restrictions until certain concessions were made by the Commissioners of Customs and Excise, which allowed specially denatured alcohol to be used duty-free. The embargo upon importation of Canadian cattle had greatly reduced the supply of fresh raw pancreas material in this country and a good deal of improvisation and initiative have been necessary for the effective organisation of the available supply of raw material during recent months. The only limit now placed, and likely to be placed for some time, upon British production is the limitation of raw material available under suitable conditions.

In the meantime, Messrs. Eli Lilly and Co., of Indianapolis, Indiana, working under agreement with the University of Toronto, have been proceeding towards large-scale production since the early summer of 1922. By the courtesy of the University, this firm was able to submit samples of their insulin product to the Medical Research Council in February last for testing. At the end of March, Messrs. Eli Lilly found themselves in a position to offer the Medical Research Council a considerable supply of their product for distribution in this country under similar restrictions to those at present governing distribution during a provisional period in the United States and Canada—namely, to approved hospitals and to physicians with approved clinical facilities. In view of the urgency of the demand, the Council cabled for this supplementary American supply, of which the first consignment is expected to arrive during the present week. It is a remarkable coincidence that the products of large-scale American production should become available here only a few days after the first commercial supply of British insulin.

American and British Sources.

The Medical Research Council have arranged that the insulin of American manufacture should be distributed by those British firms whose own product is already available or may hereafter become available and the amount distributed by each British firm will be in proportion to the volume of its own production. Both British and American insulin will be sold here only under that name (except for the addition of mark or brands indicating origin). A maximum selling price has been fixed by agreement with the Council for a short provisional period, and there is

¹ THE LANCET, Nov. 18th, 1922, Feb. 24th, 1923.

probability of its being reduced at an early date. The British firms have adopted a method of purification of the final product worked out by Dr. Dudley at the National Institute for Medical Research. By this method it is possible to get rid of over 90 per cent. of the solid matter in the crude end-product of the original process, and it allows the manufacturers to offer the active principle in the form of hydrochloride in highly concentrated form, freed from accidental irritants and other substances. For the avoidance of improper exploitation of this valuable process, provisional application has been filed by Dr. H. W. Dudley, jointly with the Medical Research Council, for patent rights. It is probable that in the near future the American supplies will be submitted to the same process and offered in the same form.

All the supplies now available have passed suitable laboratory and clinical tests for purity, potency, and sterility. The physiological unitage originally indicated by the first producers of insulin in the University of Toronto has not been retained. By agreement with the University, the American manufacturing firm has made current in the United States a unit having the approximate value of one-third of the original Toronto unit. The Medical Research Council have decided to adopt this smaller unit, so that all the insulin now made available in this country, whether British or American, will be standardised to a common unit value. Every batch put upon sale, of whatever origin, will be biologically tested under the supervision of the Council, and every preparation sold must bear a number corresponding with that of the batch from which it has been drawn.

Distribution of the Available Supply.

For a provisional period the Council have retained, under their agreements with the manufacturers, control over the distribution of the commercial supplies analogous to that exercised by the University of Toronto over the products of American manufacture. It is clearly desirable, apart from other considerations, that now, and at least until the supply is more than equal to the demand, the available insulin shall be distributed so as to reach those patients whose need is greatest, and so as to be placed in the hands by which it can be administered to the greatest effect and with the least waste. Difficult problems arise here of interest and importance to the public, to the medical profession, and to hospital administrations.

The research work, both in the laboratory and in the wards, which has brought manufacture in this country to its present pitch, and all the connected problems of standardisation and further research work, fall properly within the sphere of the Medical Research Council. These medical administrative problems of distribution, on the other hand, have been submitted by the Council to the Minister of Health within whose responsibility they properly lie. Having regard to the special nature and urgency of the occasion, the Minister has appointed a small Committee to advise him upon the subject, composed as follows: Sir George Newman (chairman), Dr. R. A. Bolam, Sir Walter Fletcher, Sir Humphry Rolleston, Dr. Alfred Salter, M.P., Dr. G. F. McCleary (secretary) (address, Ministry of Health, Whitehall).

To avoid any unnecessary delay, provisional authority had been given to the firms to distribute insulin to various large hospitals, and the first British-made insulin was actually so supplied on April 12th. On the advice of this Committee, manufacturers will be directed, during the present period of restricted production, to supply insulin only to those hospitals and to those registered medical practitioners who have proper facilities at their command for making accurate blood-sugar determinations.

Restrictions Imposed.

Each hospital and practitioner so supplied will undertake to observe the following restrictions upon the use of insulin:—

1. Careful correlation will be made of the diet, of the blood-sugar changes, and of the insulin dosage in each case. For

at least one group of cases it is known already that the insulin dosage can be reduced progressively with suitable adjustment of diet. This reduction allows economy of insulin, besides the advantage it may bring to the patient.

2. Insulin will not be given to those whose symptoms can be controlled by moderate restrictions of diet. There should be no luxury use of insulin till supplies are abundant.

3. It is understood, of course, that in emergency and apart from the careful correlation just mentioned, insulin will be given to those in diabetic coma or those nearly approaching it, and it may be given to those with diabetic symptoms needing special preparation for some surgical operation.

4. Care will be taken to avoid the danger of giving insulin to non-diabetic cases (e.g., to patients with renal glycosuria).

Hospitals or practitioners desiring supplies for immediate use should apply to one or other of the British firms named above.

It is hoped that at a very early date preliminary communication will be made of the results of the insulin treatment which has been in progress during the past months in the hospitals at London, Edinburgh, Glasgow, and Sheffield, named in the earlier statement by the Council, in order that experience gained in this clinical research work may be put at the disposal of the profession for their information and guidance.

Medical News.

CONJOINT EXAMINATIONS IN IRELAND BY THE ROYAL COLLEGE OF PHYSICIANS AND THE ROYAL COLLEGE OF SURGEONS.—The following candidates passed the spring examinations:—

Third Professional Examination.—Anna Allen, P. M. Banim, Moira E. Connolly, Bridget Crawford, T. A. Cronhelm, J. Dalrymple, Pauline M. Dooley, R. G. Freeman, V. D. Gordon, J. A. Hynes, Wilhelmina C. Maguire, M. A. Monahan, A. French O'Carroll, W. O'Connor, and P. C. Raftery.

Final Professional Examination.—Thomas Aitken Austin, Alan Plewman Brown, Josephine Alcorn Carson, Maurice Cremin, Victoria Elizabeth Davidson, Evelyn Sylvia Delany, John Francis Devlin, Douglas Arthur T. Eaton, Isaac Jacob Eppel, Thomas Valentine Fitzpatrick, Sydney George Gilmore, Alphonsus Joseph Harte, Michael Joseph O'Riordan, Robert Dobbs Seale, and Vincent Francis Walsh.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH, ROYAL COLLEGE OF SURGEONS OF EDINBURGH, AND ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—At examinations recently held the following were successful:—

THIRD EXAMINATION.

Alastair F. B. Mackay, Eleanor P. Topping, William A. Kemp, Charles Campbell, John S. Caldwell, Radcliffe D. Jones, Joseph F. Sweeney, Carapiet Aviet Basil, David D. Radford, Alexander J. M. Findlater, Harold V. R. McKinlay, Constance P. H. Hunter, James D. Edminson, Frederick Blacklee, William Rogers, John C. Shiach, Mollie F. Churcher, Cecil J. R. Morrison, Adam S. Gordon, Albert E. Williamson, Moss M. Bronstein, Gavin J. Bell, Donald L. Crawford, Petrus Johannes Badenhorst, James K. Hunter, George R. Mitchell, and Alexander S. Ballantine.

Pathology.—Leslie V. Sherrin.

Materia Medica.—John B. Hutchison, John Lees, William McKim, William A. Evans, Margaret M. McCusker, Joseph Horsham, Joseph B. Stromier, Winifred G. Price, David D. H. Craig, John M. Coutts, Sarah Boyle, Robert H. McKinnon, John J. MacKenzie, Irma E. L. Mackenzie, David Lumsden, Lewis Mackenzie, Douglas B. Craig, John J. McKenna, and Charles E. Millen.

FINAL EXAMINATION.

The following candidates having passed the Final Examination, were admitted L.R.C.P.E., L.R.C.S.E., L.R.F.P. & S.G.:—

James M. McLintock, Minnie E. McMurray, John M. Cockburn, Behari Lal Chopra, Nicholas J. Laubscher, William N. Stirling, George Abeysinche Weera Wickramasuriya, Daniel Maximos, Dinbai Jhangar Dubash, Edward R. C. Walker, Philip G. Bainbridge, William Paris, Jonathan Johan du Pre le Roux, James H. Murrell, Sarel Jacob Reich, Daivasikamany Kanaka Sabhesan, Ernest Levine, Louis Jaffit, John J. Mann, Don Valentine Walpole, and James S. Bizzett.

Medicine.—Hari Prasanna Sen, Wilhelmina C. Storrie, Ruby S. Beveridge, Eliazar Gelfer, Donald G. Coutts, Martha D. Devon, Maurice N. Gelb, George A. P. McConey, and Duncan R. Nicol.

Surgery.—Cyril A. Paulusz and Maurice N. Gelb.

Midwifery.—Thomas F. Kelly, Ruby S. Beveridge, Cyril A. Paulusz, William E. Haydon, Martha D. Devon, George A. P. McConey, and Thomas J. Muir.

Medical Jurisprudence.—John A. McCann, John S. Whiteside, Joseph McAuley, Anna G. Laubscher, Darwish Mustafa Safwat, Eliazar Gelfer, Harold V. R. McKinlay, Arthur W. H. Noble, James Ryan, Lauchlan McLean, and Mary C. Semple.

HUNTERIAN SOCIETY.—The annual general meeting will be held on April 23rd, at 8.15 P.M., in the Small Hall, the Royal Society of Medicine, 1, Wimpole-street, London, W. 1. Dr. Hingston Fox, who for some years has been engaged in compiling the centenary history of the society, will discourse on some of the more interesting topics and personalities connected with the society under the headings: Jonathan Hutchinson the Naturalist, Henry Gawen Sutton the Philosopher, and Hughlings Jackson the Seer. The address will be illustrated with the epidiascope.

THE ROYAL SOCIETY OF MEDICINE: The Sir William Dalby Memorial Prize.—Lady Dalby, widow of the late Sir William Dalby, has handed to the Royal Society of Medicine £500 for the purpose of providing a perpetual memorial of her distinguished husband. The trust deed provides that the interest on the capital sum is to be accumulated for five years when the product, less expenses, is to be awarded as a prize to the person who during the previous five years has produced the best original work, done or published, for the advancement of otology. The prize will be awarded by the Council of the Royal Society of Medicine upon the recommendation of the president and vice-presidents of the Section of Otology.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—A quarterly Council was held on April 12th, Sir Anthony Bowlby presiding.—The Secretary reported the death on March 18th, at the age of 61, of Sir William Thorburn, and a vote of condolence was passed.—The President reported that the vacancy in the Council thus occasioned would be filled at the meeting of the Fellows on July 5th next, and that the vacancy on the Court of Examiners would be filled at the next meeting of the Council on May 10th.—A report was read from the Secretary respecting candidates found qualified for the Diploma of Member, and diplomas were granted to the following four candidates: Bernard Bourke (Dublin), Emmie Dorothy Fenwick (Royal Free and St. Mary's), Marjorie Annie Godfrey (Royal Free), and Naja R. Mucadam (Bombay and Royal Free).—A report was read from the Secretary respecting candidates found qualified for the diploma of the Licence in Dental Surgery, and a diploma was awarded to Mr. D. E. Thomas (Pennsylvania and Middlesex).—It was reported that the Jacksonian Prize for the year 1922 had been awarded to Mr. Sidney Forsdike for an essay on the Effects Produced by Radium upon Living Tissues, with Special Reference to its Use in the Treatment of Malignant Diseases.—The Council decided that the subject for the Jacksonian Prize for 1923 would be the Pathology, Diagnosis and Treatment of (F)osphageal Obstruction.—Mr. Douglas Gabell was elected a Member of the Board of Examiners in Dental Surgery.—Sir Arthur Keith was appointed Thomas Vicary lecturer for the ensuing year.

OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM.—The annual congress will be held from April 26th to 28th at the Royal Society of Medicine, 1, Wimpole-street, London, W. 1, on Thursday, April 26th, Dr. A. Maitland Ramsay presiding. On the first morning the President will give his opening address. Papers will be read by Mr. E. Treacher Collins and by Sir William Lister on the Ætiology of Angioid Streaks in the Fundus Oculi, and by Mr. R. Affleck Greeves and Mr. R. Foster Moore, on a Series of Consecutive Cases of Cataract Extraction by Barraquer's Method. Mr. D. V. Giri will offer Some Observations on Intracapsular Extraction of Cataract, with Description of a Simple Technique; and Mr. Charles Killick will discuss a Series of a Hundred Cases of Cataract Extraction Removed under a Subconjunctival Bridge. In the afternoon a discussion on the Disorders of the Blood and their Ophthalmological Manifestations will be opened by Sir Humphry Rolleston, Sir Frederick Andrewes, F.R.S., and Dr. W. C. Souter. Mr. R. Rutson James and Dr. A. J. Ballantyne will speak, and the latter will communicate a paper entitled Some Illustrations of Retinal Vascular Disease, and of Fundus Lesions in Diseases of the Blood. At 5 P.M. the Bowman lecture will be delivered by Prof. George E. de Schweinitz, president of the American Medical Association, on Certain Ocular Aspects of Pituitary Body Disorders, mainly exclusive of the Usual Central and Peripheral Hemiopic Field Defects. At 7.30 P.M. members will dine together at the Langham Hotel, Portland-place, London, W. 1. On April 27th, in the morning, a discussion on the Diagnostic Significance of Proptosis will be opened by Mr. Wilfred Trotter, Mr. Herbert Fisher, and Dr. Angus MacGillivray. The following also intend to speak: Mr. Percy Flemming, Dr. T. H. G. Shore, and Mr. P. G. Doyne. Papers will be read by Mr. W. T. Holmes Spicer on Secondary Corneal Opacities, and by Mr. F. A. Williamson-Noble on Macular Changes in Thrombosis of the Central Retinal Vein. In the afternoon a clinical meeting will be held at the London Hospital. In the evening demonstrations will be given by Mr. Humphrey Neame, Mr. F. A.

Ross and Dr. Shephard-Walwyn, Mr. B. T. Lang, Mr. A. Beck Cluckie, Mr. Basil Graves, Mr. John Rowan, Mr. G. F. Alexander, Mr. Leslie Buchanan, and Mr. R. E. Wright. On April 28th papers will be contributed by Dr. Angus MacGillivray, Mr. Leslie Buchanan, Mr. Percival J. Hay, Mr. Humphrey Neame, Mr. W. B. Inglis Pollock, Mr. Lindsay Rea, and Mr. G. F. Alexander.

TUBERCULOSIS SOCIETY.—An ordinary meeting will be held on Monday, April 23rd, at 8 P.M., at the Margaret-street Hospital, Margaret-street, London, W. 1, when Dr. A. K. Chalmers, M.O.H. for Glasgow, will read a paper on Housing and Tuberculosis.

ROYAL INSTITUTION.—On Tuesday, April 24th, Sir Arthur Keith will deliver at 3 P.M. a third lecture on the Machinery of Human Evolution. On Saturday, April 28th, at 3 P.M., Dr. Leonard Williams will deliver the first of two lectures on the Physical and Physiological Foundations of Character. The Friday evening discourse on April 27th, by Mr. C. V. Boys, will be on Measurement of the Heating Value of Gas; and that on May 4th by Prof. Soddy will be on the Origins of the Conception of Isotopes.

MEDICAL HYDROLOGY: LECTURES AND CLINICAL TEACHING AT THE UNIVERSITY OF LONDON.—A special course of lectures and demonstrations has been arranged by the London University Extension Board and a committee of the International Society of Medical Hydrology, and will be held at the laboratories of the University of London at South Kensington, and at two of the British spas, from May 29th to June 4th. All medical men interested in the therapeutic use of waters and baths are invited to take part in this course, of which full particulars will shortly be issued.

CONFERENCE ON THE MILK QUESTION.—A conference will be held at the house of the Royal Society of Arts, John-street, Adelphi, London, W.C. 2, on April 25th, at 4.30 P.M. Short papers will be read as follows: (1) The Arguments for Maintaining an Open Market for Fresh Milk, by Dr. R. Stenhouse Williams; (2) Changes in the Digestibility and Nutritive Value of Milk Induced by Heating, by Prof. J. C. Drummond; (3) The Effect of Heat on Some Physiological Principles in Milk, by Dr. S. S. Zilva. A demonstration of some of the chemical changes in milk on heating to various temperatures will be given by Capt. John Golding, and Mrs. A. T. R. Mattick, M.Sc. Mr. F. D. Acland, M.P., will preside.

CONGRESS OF DERMATOLOGY AND SYPHILIS.—A congress on dermatology and syphilis will be held at Strasbourg from July 25th to 27th, preceded by a congress on cancer (July 23rd and 24th), and followed by one on leprosy (July 28th to 31st), in connexion with the Pasteur celebrations, under the auspices of la Société française de Dermatologie et de Syphiligraphie of the Comité d'organisation de l'Association des Dermatologistes et Syphiligraphes de Langue française. Clinical cases will be shown and discussions will be held on the following papers: Sensitisation and Desensitisation in Skin Affections, by Dr. Ravaut (Paris) and Prof. Spillman (Nancy); Nævo-carcinomata, by Prof. Masson (Strasbourg) and Prof. Bruno Bloch (Zurich); the Treatment of Syphilis in the Early Stage, by Dr. Queyrat (Paris) and Prof. Malvoz (Liège); and the value of various ways of introducing Medicaments in the Treatment of Syphilis, by Dr. Milian (Paris) and Dr. Bodin (Rennes). Further information may be obtained from the president of the committee of organisation, 2, quai St. Nicolas à Strasbourg, to whom fees and communications must be sent before June 1st.

NATIONAL HEALTH INSURANCE IN IRISH FREE STATE: HOUSING COMMITTEES.—Our Dublin Correspondent writes: The National Health Insurance Commission recently obtained authority from the Free State Government to set up an advisory committee. In its letter of authority to set up the committee the Government was clear in insisting that the committee should limit itself strictly to insurance work and not trench on the functions of other Government departments. The first meeting of the advisory committee was held on April 12th, Sir Joseph Glynn, chairman of the commission, presiding. The committee includes representatives of the approved societies, of the insurance committees, of the medical and nursing professions, of the hospitals, and of the Labour party. The medical profession is represented (temporarily) by Mr. T. Hennessy and Dr. R. J. Rowlette. Other medical men present representing hospital interests were Mr. Horace Law and Dr. M. F. Cox. A discursive discussion took place on various points regarding the administration of the Insurance Acts, and resolutions were passed: (1) drawing attention to the need for the establishment of a system of medical treatment for the classes affected by the Insurance Acts; and (2) asking that provision should be made for carrying on medical research.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

THE BUDGET.

MR. BALDWIN'S first Budget, introduced on April 17th in the House of Commons, provides for a total expenditure of 816 million pounds and a probable surplus of 36 million pounds. The expected concessions were realised for various classes of the community—6d. off income-tax, 1d. off beer, the corporation profits tax halved, some abatement on mineral waters and ciders, and reduction of postal charges. An unexpected relief was offered to telephone subscribers. Mr. BALDWIN proposed to reserve 40 million pounds for sinking funds to cover obligations arising during the year, including interest on the American debt. "Our debt," he said, "to-day is insistently knocking at the door of this generation," and he did not regard his provision as likely unduly to ease the circumstances of our grandchildren.

HOUSE OF COMMONS.

WEDNESDAY, APRIL 11TH.

Payments to Panel Practitioners.

Sir KINGSLEY WOOD asked the Minister of Health whether he contemplated any alteration in the terms of payment to doctors on the panel lists; and whether he proposed to consult with representatives of the approved societies on the matter.—Mr. NEVILLE CHAMBERLAIN replied: Before the expiry of the present agreement at the end of this year both the terms of service and the remuneration of insurance practitioners will have to be reconsidered. In reply to the second part of the question, the Insurance Consultative Council have already been consulted in regard to the terms of service and will be consulted also as to the rate of remuneration. There is no other body representative of all the approved societies, but I shall be prepared to receive representations from the principal groups before coming to a final decision.

Sir KINGSLEY WOOD: Is the right hon. gentleman aware that representatives of the medical profession have declined to meet representatives of approved societies to discuss this matter?—Mr. CHAMBERLAIN: No, Sir.

Major MACKENZIE WOOD: Does the right hon. gentleman think that this Council represents the approved societies?—Mr. CHAMBERLAIN: It is an elected body.

Sir KINGSLEY WOOD asked the Minister of Health the number of doctors on the panel list, and the approximate annual amount they received for their services.—Mr. CHAMBERLAIN replied: The total number of insurance practitioners in England and Wales according to the latest return is 12,588. The total payments to them in 1922 amounted to approximately £6,750,000.

THURSDAY, APRIL 12TH.

Physique of School-children at Whitehaven.

Mr. GAVAN-DUFFY asked the Minister of Health if his attention had been drawn to the statements made in the annual report of the medical officer of health for the borough of Whitehaven for 1922 to the effect that the physique of the school-children showed that there had been an appreciable deterioration from the standard of 1921, and that this was due to the low wages earned by the miners, resulting in a deterioration of the quality and quantity of the food supplied to them; and whether he would take immediate steps, by the rigid administration of the Maternity and Child Welfare Acts and the Provision of Meals Act, to check any further development of this physical deterioration among the children in Whitehaven and district.—Mr. NEVILLE CHAMBERLAIN replied: I have seen the report of the school medical officer, which is apparently the report referred to by the hon. Member. The question what meals should be provided by a local education authority to children attending public elementary schools in their area is one for the decision of the authority under Section 82 of the Education Act, 1921, and in the same way the administration of the Maternity and Child Welfare Acts is primarily a matter for the local authority. I may say, however, that the scheme of the Whitehaven town council under the latter Act includes the provision of milk in necessitous cases, and I have approved their estimate for this purpose.

Pension Cancellations on Medical Grounds.

Mr. HAYDAY asked the Minister of Pensions what was the number of pensions cancelled during the 12 months ending Dec. 31st, 1922, owing to change of diagnosis or change of entitlement on medical grounds, and what was the average duration of the pensions so cancelled.—Major TRYON replied: Out of some 600,000 cases which came up for reassessment during 1922, it was found necessary to

CHELSEA HOSPITAL FOR WOMEN.—The fifty-second annual general meeting of the governors will be held at the hospital on Tuesday, April 24th, at 4 P.M., when an important statement of policy will be made.

ILLUMINATING ENGINEERING SOCIETY.—A meeting will be held at the House of the Royal Society of Arts (John-street, Adelphi, London), at 8 P.M., on Tuesday, April 24th, when Mr. Leon Gaster, F.J.I., will open a discussion on Some Problems in the Lighting of Printing Works.

DONATIONS AND BEQUESTS.—Besides a gift of £2000 in connexion with the treatment of cancer at Hull Royal Infirmary, Mr. T. R. Ferens has placed the interest of £3000 at the disposal of the Governing Board to meet the working expenses involved. The principal itself will eventually revert to the infirmary.

LONDON (R.F.H.) SCHOOL OF MEDICINE FOR WOMEN (UNIVERSITY OF LONDON).—A course of six post-graduate lectures on Ante-Natal Care will be given at the school, on Tuesdays, at 5 P.M., by Prof. A. Louise McIlroy, the first lecture on May 1st dealing with the Maintenance of Physiological Conditions during Pregnancy.

LONDON HOSPITAL MEDICAL COLLEGE (UNIVERSITY OF LONDON).—A course of ten lectures on Psycho-Neuroses will be delivered in the anatomical theatre of the College by Dr. Millais Culpin, on Tuesdays and Fridays at 5.15 P.M., beginning May 1st. The lectures will deal with Instinct and Emotion; Dissociation; the Unconscious; the Dynamics of the Unconscious; Dreams; Symptomatology (2); Diagnosis; Treatment (2). The last lecture of the series is on June 1st.

INSTITUTE OF PATHOLOGY AND RESEARCH, ST. MARY'S HOSPITAL.—As in previous years a course of lectures on Pathological Research in Relation to Medicine has been arranged during the summer session at St. Mary's Hospital. The lectures will be given in the Bacteriological Department of the Institute on Thursday afternoons at 4.30 P.M., and the course will commence next Thursday with a lecture from Sir Almroth Wright, the principal of the Institute. The lectures are open to the medical profession and to all students in medical schools without fee; previous sessions have been largely attended and have proved of real value to the audiences. Subsequent lectures to be given by Prof. W. Bulloch, Dr. H. H. Dale, Prof. F. G. Hopkins, Dr. Bernard Hart, Dr. Leonard Hill, Dr. Alexander Fleming, and Prof. G. Dreyer will be announced in our Medical Diary.

SWEDISH SOCIETY OF PHYSICIANS.—The Section of Laryngology of the Swedish Society of Physicians has invited British representatives to deliver in Stockholm lectures on subjects with which their work has been identified. The meeting has been arranged for Whitsuntide and the following is a list of those who have accepted invitations, with the subject of their communication: Mr. Arthur Cheate: The Aetiology and Prevention of Chronic Middle Ear Suppuration. Sir St. Clair Thomson: Cancer of the Larynx. Dr. Logan Turner: The Occurrence of Metastatic Tumours in the Larynx, with the description of a case. Dr. Brown Kelly: The Significance of Certain Pharyngeal Signs and Symptoms.

On their way to Sweden the lecturers may join in the Summer Meeting of the Dutch Oto-Laryngological Society at The Hague on May 12th and 13th.

LEICESTER ROYAL INFIRMARY: ANNUAL REPORT. The 150th report of the infirmary, submitted to the annual meeting on April 18th, points out some directions which medical progress is likely to take in the near future, especially in connexion with the prevention of disease and the part which hospitals will play in dealing with the early symptoms of curable maladies. During the year under notice (1922) 3627 new in-patients were treated as compared with 3618 in 1921, while the average number of beds occupied was 255 and 252.5 in the two years respectively. The average cost per bed was £182 and the average cost per in-patient £11 9s. 10d. In the out-patient department there was an increase both in ordinary attendances and in accident cases over the figures for the preceding year, motor transport and other means of speedy locomotion being responsible for the large increase in the casualty category. In the venereal diseases department there were 429 males and 239 females treated among new cases; male attendances numbered 9990 and female 4972, the corresponding figures for 1921 being 505, 296, 10,792, and 5216 respectively. The total income for the year was £59,786, as against £61,112 in 1921, and the expenditure £62,452, as compared with £67,093 in 1921. Towards the £100,000, for which an appeal has been made on behalf of a new south wing, to provide for 93 patients, 66 new bedrooms for nurses, and an enlargement of the laundry, £60,000 have been already collected. To mark the third jubilee of the institution it is suggested that contributions should be sent in multiples of 12s. 6d., being 1d. a year since the foundation.

cancel entitlement to pension on medical grounds in less than one-half of 1 per cent. I regret that I am not in a position to state the average duration of these pensions.

Medical Evidence and Pension Claims.

Mr. HAYDAY asked the Minister of Pensions whether applications under Article 9 of the Warrant were now rejected unless the applicant could produce evidence of continuous medical treatment since the date of his discharge or demobilisation; and, if so, whether he had considered the hardship that was likely to arise from a man's inability to produce certificates covering a long period.—Major TRYON replied: The answer to the first part of the question is in the negative. While connexion between the disability claimed and the man's military or naval service can obviously best be established by medical evidence covering the period between discharge and the date of the claim, full weight is always given to evidence of other kinds which is frequently found sufficient to establish a claim to pension.

Pensioners Suffering from Bronchitis and Asthma.

Mr. CAIRNS asked the Minister of Pensions whether he was aware that there was a general impression that pensioners suffering from bronchitis and/or asthma were seriously under-assessed in respect of their degree of disablement; what was the number of pensioners in receipt of pension for bronchitis and/or asthma; and whether, owing to the nature of these diseases and the difficulty in arriving at a correct assessment during the two-minutes examination by a medical board, he would issue instructions that pensioners whose disability was bronchitis and/or asthma should be admitted to hospital for observation and that the re-survey board should be held prior to their discharge from the institution.—Major TRYON replied: The approximate number of pensions in payment in respect of affections of the respiratory system (other than tuberculosis) is 41,000. I am not aware of the impression referred to, nor do I consider that any such views, if held, would be well founded. Procedure on the lines suggested in the last part of the question has been in force for some time, and is acted upon wherever the circumstances of the case render such a course necessary. I may add that the hon. Member is mistaken as to the time occupied by an examination by a medical board. The average time given to cases of re-examination for renewal of pensions is more than a quarter of an hour, and to first claims or for final award the time given is usually over half an hour.

Charges for Massage and Electrical Treatment.

Mr. ARTHUR GREENWOOD asked the Minister of Pensions whether he was aware that in the cases of officers and nurses undergoing approved home treatment the authorised fee for combined massage and electrical treatment had been reduced from 7s. per visit to 3s. 6d. per visit, and that for massage treatment reduced from 3s. 6d. per visit to 2s. per visit; that in many cases it was not possible to obtain the treatment necessary at the authorised rates; and whether, if the authorised rates were reduced, he would give the commissioners of medical services in the regions discretionary power to sanction payments at higher rates to enable patients to obtain the treatment deemed necessary.—Major TRYON replied: There has been no recent change in the approved scale of charges for massage and electrical treatment given at home. The higher fees mentioned are sanctioned when the treatment is given at the patient's own home, but where the patient attends as an out-patient at an institution for the treatment the lower rates are applicable. Officers and nurses finding difficulty in obtaining prescribed massage and electrical treatment within the authorised fees should communicate with the commissioner of medical services of the region, who will make arrangements for the provision of suitable treatment at approved charges.

A1 Recruits and Disablement Claims.

Mr. MIDDLETON asked the Minister of Pensions whether he was aware that the principle of accepting liability for subsequent disabilities of men who passed A1 on enlistment had been admitted by the United States Government; and whether he was prepared to consider the application of the same principle to disabled men in this country.—Major TRYON replied: I am not aware that any such principle has been admitted by the United States Government. If the hon. Member has in mind the recent amendments to the United States War Risks Insurance Act, I am advised that under that Act, as amended, liability for subsequent disabilities in the case of men passed fit on enlistment is confined to cases of disabilities occurring prior to or within one year of discharge from the United States Forces, or to disabilities which are up to a specified date certified as being traceable to injury existing at the time of discharge. The liability referred to is, therefore, strictly limited. In my department it is the practice, in the absence of any record of impairment at the time of enlistment, to regard acceptance for military service as *prima facie* evidence of fitness at that date. This principle holds good in all cases where a claim is made for

any disability within seven years of the man's discharge. I consider, therefore, that the practice of my department in this respect is fully as favourable to the man as that adopted by the United States of America, if, indeed, it is not more favourable, and I am not prepared to make any alteration in it.

French Pensions Law and Attributability.

Mr. LAWSON asked the Minister of Pensions whether his attention had been drawn to Article 5 of the French War Pensions Act of March 31st, 1919; whether he was aware that the Article provided that all diseases from which a soldier or sailor was ascertained to be suffering during the period of his service or during the six months following his discharge should, in the absence of proof to the contrary, be presumed to have been contracted or aggravated as the result of the fatigue, dangers, or accidents of service; and whether, in any amending legislation he might introduce, he would include a clause presuming origin of disability and placing the onus of proving the contrary on the Ministry of Pensions.—Major TRYON replied: I am aware of the Article of the French Pensions Law to which the hon. Member refers, but a reference to the concluding paragraph of that Article shows that its provisions are a good deal more restricted than is suggested by the hon. Member, since, in the case of discharged men, it was limited to those who applied within six months of the publication of the law, that is, before Sept. 30th, 1919, for a certificate of their disease or disability. My department has always acted on the view, in the case of men invalided from the Service, that a disability incurred while in military service affords a *prima facie* suggestion that it was connected with his service, and unless it is clear that the balance of probability is against the man's claim, the benefit of the doubt is given to him. I am not prepared to adopt the hon. Member's suggestion.

Sunderland Pensions Hospital.

Mr. ROBERT RICHARDSON asked the Minister of Pensions whether it was proposed to close the Ministry of Pensions Hospital, Sunderland; whether his attention had been drawn to the fact that the civil hospitals in the counties of Durham and Northumberland had long waiting lists of civilian patients and were unable to deal promptly with pensioners; whether the medical officers of the northern region were in favour of the closing of the Sunderland hospital; and whether, if it be decided to close this hospital, other hospital accommodation would be provided in the county of Durham for pensioners.—Major TRYON replied: Owing to the decreasing requirements of my department in the northern region, arrangements have been made to close this hospital gradually. This step was not taken without the fullest consideration of all the circumstances and, after consultation with my medical advisers, I am satisfied that ample facilities will remain for providing without delay all necessary treatment.

Serious Accidents in Shipbuilding Yards.

Mr. JOHN DAVISON asked the Secretary of State for the Home Department whether, in view of the number of serious accidents, fatal and otherwise, which occur in shipbuilding and ship-repairing yards, he had come to any decision to institute a special inquiry into the means necessary to secure a higher standard of safety.—Mr. BRIDGEMAN replied: Yes, Sir; I have decided to appoint a departmental committee whose terms of reference will be "to inquire into the circumstances and causes of accidents in shipbuilding and ship-repairing and to report what further measures for their prevention are desirable." My hon. friend the Parliamentary Under Secretary of State (Mr. Godfrey Locker-Lampson) has agreed to act as chairman, and the other members of the committee will consist of representatives of the employers and workers affected, and a representative of the Factory Department of the Home Office.

Tuberculosis among School-children.

Mr. CECIL WILSON asked the President of the Board of Education whether his attention had been called to the report of the Sheffield school medical officer in which he stated that tuberculosis was a very frequent cause of ill-health among school-children, and in which he further compared the rate of exclusion per 1000 in the larger elementary schools from which it appeared that in schools where there was poverty the rate of exclusion showed an average in 1922 of nearly 15.0 per 1000, and in schools where there was not poverty the rate was only 2.0 per 1000; and whether these figures applied generally to schools throughout the country.—Mr. EDWARD WOOD replied: I have received the usual official copy of the report in question, and the figures relating to the incidence of tuberculosis among school-children at Sheffield will be reviewed with other similar returns as usual in the annual report of the Chief Medical Officer to the Board. I am advised that the returns for Sheffield are not representative of the country as a whole. The hon. Member will find the subject discussed in the annual report of the Chief Medical Officer for 1920, published in August, 1921, pages 134-145.

Patients in Poor-law Infirmaries.

Mr. HAYDAY asked the Minister of Health what was the average number of patients in Poor-law infirmaries in this country; what was the average number of children boarded out and in children's homes; what was the actual number of Poor-law infirmaries visited by women inspectors last year as distinct from the number of visits paid; whether any Poor-law infirmaries were inspected by male inspectors; what were the qualifications required for the post of superintending woman inspector; and what was her basic salary.—Mr. NEVILLE CHAMBERLAIN replied: I regret that I am unable to state the average numbers asked for in the first two parts of this question, but on Jan. 1st last there were approximately 84,000 patients in infirmaries and in the sick wards of other Poor-law institutions; there were 9800 children boarded out and 32,000 children in Poor-law institutions provided wholly for the reception and maintenance of children. 206 infirmaries were visited by women inspectors last year, and the infirmaries are also inspected by the male general inspectors and by medical officers of my department. The superintending woman inspector is selected from the women inspectors, who are required to be fully trained nurses. Her basic salary is £100—£15—£450.

Kidderminster Hospital.

Mr. WARDLAW-MILNE asked the Minister of Health whether he was aware that, under an arrangement with the Worcester County Council, the committee of the Kidderminster Infirmary and Children's Hospital had hitherto provided treatment for about 85 persons annually suffering from venereal diseases and had further provided in-patient treatment for about 28 persons; whether he was aware that the closure of the in-patient department of the infirmary was now contemplated; if so, whether, seeing that such closure might necessitate the transfer to Worcester of patients who might be dangerously ill, he would state what saving in expenditure the closure of the in-patient department would bring about; and whether, in view of the risk to the patients incurred by the conveyance to Worcester, he would reconsider his decision in the matter.—Mr. NEVILLE CHAMBERLAIN replied: I am aware of the proposals of the Worcestershire County Council in this matter, and I am in communication with the council as to the arrangements which they propose to make for cases needing immediate in-patient treatment. The saving in expenditure due to the proposals is estimated to amount to more than £100 per annum.

MONDAY, APRIL 16TH.

Public Health Commissioner in India.

Sir JOHN HEWETT asked the Under Secretary of State for India whether any decision had been arrived at on the proposal of Lord Inchcape's Committee to abolish the appointment of Public Health Commissioner in India.—Earl WINTERTON replied: The answer is in the negative.

Slum Dwellings in England and Wales.

Mr. TREVELYAN THOMSON asked the Minister of Health what was the approximate number of slum dwellings and of houses not reasonably fit for human habitation at present in occupation in the whole of England and Wales, based on the returns which he had from certain parts of the country.—Mr. NEVILLE CHAMBERLAIN replied: Reports received from the medical officers of health of 1665 local authorities for the year 1921 show that 18,321 houses were reported as unfit for human habitation, and 257,686 houses were found not to be in all respects reasonably fit for habitation. It is not possible to give the number of these houses actually occupied at the time the reports were made.

Daily Death-Roll from Tuberculosis.

Mr. TURNER asked the Minister of Health what was the daily death-roll from tuberculosis.—Mr. NEVILLE CHAMBERLAIN replied: The total number of deaths in England and Wales from all forms of tuberculosis in 1922 was 42,777, or an average of 117 per day.

Licence Duty on Ambulance Cars.

Mr. WESTWOOD asked the Chancellor of the Exchequer if he was aware that licence duty was being demanded for ambulance cars used by education authorities for conveying physically and mentally defective children to and from school; and would he consider favourably that such cars be exempted from licence duty.—Colonel ASHLEY (for the Minister of Transport) replied: Whether or not the vehicles referred to can properly be termed "ambulances" is a matter of law to be decided on the facts of the case. I am not prepared to recommend any extension of the scope of the exemption for ambulance services set out in Section 13 (4) of the Finance Act, 1920.

Increase in Nystagmus.

Mr. ALBERT BENNETT asked the Secretary for Mines if he was aware of the large increase in the number of cases of nystagmus in this country, particularly in recent years;

and what steps he was taking to deal with the matter.—Lieut.-Colonel LANE-FOX replied: As regards the numbers of cases I would refer the hon. Member to the figures given in my reply of March 26th. The whole matter is under inquiry by a committee appointed by the Medical Research Council. A first report was issued last year and another is in course of preparation. The main remedial measure so far suggested is improvement of illumination in mines, and on this very difficult problem the Miners' Lamps Committee has been at work for five years and has published memoranda containing useful suggestions. Everything that the department can do to stimulate improvement in lighting is being done, and I am glad to know that this important subject is more and more engaging the attention of the industry.

TUESDAY, APRIL 17TH.

Duty on Patent Medicines.

Major ENTWISTLE asked the Chancellor of the Exchequer if he was aware that, according to the construction placed by the Customs and Excise Department upon the provisions of Section 3 of the Patent Medicine Stamp Duty Act, 1812, makers of chemical preparations sold under a fancy name, by not claiming proprietary rights, were able to avoid the incidence of the ad valorem patent medicine stamp duty; and whether, in view of the large loss to the revenue resulting therefrom, he would take necessary steps to ensure the payment of the duty in such cases.—Major BOYD-CARPENTER (Financial Secretary to the Treasury) replied: The question whether any particular medicine is liable to medicine stamp duty depends on a number of considerations. If the hon. and gallant Member will furnish me with particulars of the cases he has in mind I will have inquiry made.

Cost of Health Insurance Administration.

Mr. BUTTON asked the Chancellor of the Exchequer if he could supply the relative costs of administration of national health and unemployment insurances per person insured.—Major BOYD-CARPENTER replied: The total cost of administration (central and local) in the two cases are at present—National Health Insurance, 6s. 8d. per insured person; Unemployed Insurance, 7s. 1d. per insured person.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Monday, April 23rd.

GENERAL MEETING OF FELLOWS: at 5 P.M.

Discussion on The Aetiology and Treatment of Osteoarthritis and Rheumatoid Arthritis, to be opened by Sir Archibald Garrod, followed by Dr. F. J. Poynton, Dr. Maurice Cassidy, and Dr. A. F. Hurst.

ODONTOLOGY: at 8 P.M.

Paper:

Dr. C. F. Sonntag: On Some Points in the Comparative Anatomy of the Mouth and Tongue.

Casual Communications:

Mr. G. J. Harborow: A Case of Unerupted Incisors and Canines in a Male, aged 59.

Mr. E. Sprawson: The Vascular Supply of the Enamel Organ of *Felis domestica*.

Tuesday, April 24th.

MEDICINE: at 5.30 P.M.

Short Papers:

Dr. Claude Goulesbrough: Osteo-arthritis of the Spine.
Dr. H. Letheby Tidy: Glandular Fever and Infective Mononucleosis.

Thursday, April 26th.

UROLOGY: at 8.30 P.M.

Clinical and Pathological Evening:

Those desirous of showing specimens are requested to notify the Hon. Secretary, Mr. Girling Ball, 77, Wimpole-street, W., and to state if they require microscopes.

Friday, April 27th.

STUDY OF DISEASE IN CHILDREN: at 5 P.M. (Cases at 4.30 P.M.)
Cases will be shown.

EPIDEMIOLOGY AND STATE MEDICINE: at 8 P.M.

Paper:

Dr. T. F. Dewar: On the Incidence of Venereal Disease in Scotland.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, London, W.C.

MONDAY, April 23rd.—5 P.M., Prof. Shattock: Syphilis.

FRIDAY.—5 P.M., Sir Arthur Keith: Surgical Anatomy of the Foot.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith-road, W.

MONDAY, April 23rd.—2 P.M., Mr. Addison: Surgical Wards. 3 P.M., Mr. Simmonds: Surgical Out-patients. 3 P.M., Mr. Simson: Diseases of Women.

TUESDAY.—10 A.M., Dr. Drummond Robinson: Gynaecological Operations. 2.30 P.M., Dr. Pritchard: Medical Wards. 2.30 P.M., Mr. Tyrrell Gray: Surgical Wards.

WEDNESDAY.—11 A.M., Mr. Simson: Gynaecological Demonstration. 2.30 P.M., Mr. Donald Armour: Surgical Wards. 3 P.M., Dr. Pernet: Skin Department.

THURSDAY.—2 P.M., Mr. Bishop Harman: Eye Department. 2 P.M., Mr. MacDonald: Genito-Urinary Department. 3 P.M., Dr. Scott Pinchin: Medical Out-patients.

FRIDAY.—10 A.M., Mr. Dudley Buxton: Dental Department. 2 P.M., Dr. Burrell: Medical Out-patients. 3 P.M., Mr. Sinclair: Surgical Out-patients.

SATURDAY.—10 A.M., Dr. Saunders: Medical Diseases of Children. 10 A.M., Mr. Banks Davis: Operations on Nose, Throat and Ear. 10.30 A.M., Mr. Maingot: Surgical Pathology.

Daily 10 A.M. to 6 P.M., Saturdays 10 A.M. to 1 P.M., In-patients, Out-patients, Operations, Special Departments.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

(Demonstration of Clinical Cases at 3.30 P.M.)
MONDAY, April 23rd.—Gynaecological: Mr. J. Bright Banister.

TUESDAY.—Radiological: Dr. J. Metcalfe.

WEDNESDAY.—Throat and Nose: Mr. C. H. Hayton.

THURSDAY.—Medical: Dr. Yealland.

FRIDAY.—Surgical: Mr. E. Gillespie.

INSTITUTE OF PATHOLOGY AND RESEARCH, St. Mary's Hospital, W.

THURSDAY, April 26th.—4.30 P.M., Sir Abner Wright: On the Principles of Medical Research.

INFANTS HOSPITAL, Vincent-square, S.W. 1.

THURSDAY, April 26th.—6 P.M., Dr. Eric Pritchard: The General Principles of Feeding and Dietetics as Applied to Infants and Young Children.

UNIVERSITY OF BRISTOL POST-GRADUATE DEMONSTRATIONS (in the Medical Theatre).

THURSDAY, April 26th.—3.30 P.M., Mr. H. Chitty: The Treatment of Painful Feet.

FRIDAY (at Dorchester).—Dr. W. Swayne: Toxaemia of Pregnancy.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE LECTURES.

TUESDAY, April 24th.—4.15 P.M., Mr. J. Morley: The Indications for Operation in Goitre.

ANCOATS HOSPITAL.

THURSDAY, April 26th.—4.30 P.M., Dr. Kletz: The Diagnosis and Medical Treatment of Peptic Ulcer.

Appointments.

ALLAN, J., M.D., B.Ch. Edin., D.P.H., has been appointed Refractionist to the Greenwich and Deptford Treatment Centre (L.C.C.).

BLANDY, MARJORIE A., M.B. Lond., M.R.C.P. Lond., Assistant Physician to the Elizabeth Garrett Anderson Hospital, Euston-road, W.C.

CRICKSHANK, A., M.B., Ch.B. Aberd., Junior Resident Medical Officer at the Highbury Orthopaedic Hospital, Birmingham.

GREGOR, W., M.B., Ch.B. Aberd., House Physician to the Coventry and Warwickshire Hospital.

McFARLAND, B. L., M.B., Ch.B. Liverp., Resident Junior Medical Officer at the Liverpool Open-air Hospital for Children, Leasowe.

SHENNAN, A. H., Assistant County Medical Officer, Lindsey (Lincs.).

THOMSON, W., M.B., Ch.B. St. And., Resident Medical Officer at the Royal Mineral Water Hospital, Bath.

WALKER, J. G., M.R.C.S., L.R.C.P. Lond., Venereal Diseases Medical Officer, South Shields.

Medical Referees under the Workmen's Compensation Act: COLE, T. E. C., M.D. Oxf., for County Court Circuits Nos. 22, 36, and 53; and GREEN, E. C., M.R.C.S., L.R.C.P. Lond., and GOLDSMITH, G. H., M.D. Camb., for County Court Circuit No. 20.

Vacancies.

For further information refer to the advertisement columns.

Aberdeen, Kingseat Mental Hospital, Newmachar.—Asst. M.O. £300.

Birmingham and Midland Homoeopathic Hospital and Dispensary.—Res. H.S. £175.

Birmingham General Dispensary.—Locum for Medical Staff. £9 9s. weekly.

Birmingham, Queen's Hospital Medical School.—H.S. £70.

Brighton, Royal Sussex County Hospital.—H.S. £150.

Bristol General Hospital.—Hon. Asst. P.

Cancer Hospital, Fulham-road, S.W.—H.S. £100.

City of London Hospital for Diseases of the Chest, Victoria Park, E.—H.P. £125.

Croydon General Hospital.—Jun. H.S. £150.

Dorset Mental Hospital, near Dorchester.—Third Asst. M.O. £350.

East London Hospital for Children and Dispensary for Women, Shadwell, E.—H.S. £125.

Elizabeth Garrett Anderson Hospital, Euston-road.—Asst. Phys.

Gloucestershire Royal Infirmary.—Hon. Radiologist.

Hôpital Français, 172, Shaftesbury-avenue, W.C.—Second Res. M.O. £100.

Hospital for Sick Children, Great Ormond-street, W.C.—Clin.

Asst. M.O. in Venereal Dept. £1 1s. per visit.

Hull Royal Infirmary.—Hon. P. and Hon. S.

Kensington, Fulham and Chelsea Hospital, Earl's Court, S.W.—Hon. Dental Surg.

Lancashire County Mental Hospital, Winwick, Warrington.—Locum Tenens M.O. £7 7s. weekly.

Liverpool, Royal Southern Hospital.—Hon. Asst. P.

London Homoeopathic Hospital, Great Ormond-street, W.C.—Third Anaesthetist. £50.

Manchester Babies' Hospital, Burnage-lane, Levenshulme.—Res. M.O. £150.

National Hospital for Diseases of the Heart, Westmoreland-street, W.—Out-patient M.O. £125.

Norwich, Norfolk and Norwich Hospital.—H.S. £150.

Nottingham City Asylum.—Jun. A.M.O. £400.

Notts County Council.—Asst. Maternity and Child Welfare M.O. £500.

Plymouth, South Devon and East Cornwall Hospital.—H.S. £125.

Prince of Wales's General Hospital, Tottenham, N.—Jun. H.P. £110.

Redhill, Surrey, Royal Earlswood Institution for Mental Defectives.—Jun. Asst. M.O. £250.

Rotherham Hospital.—Sen. H.S. £250.

Royal Chest Hospital, City-road.—P.

Royal Ear Hospital, Dean-street, Soho.—Hon. H.S.

St. George's Hospital, S.W.—P. Also Asst. P.

Throat Hospital, Golden-square, W.—Hon. Registrars. Also Hon. Asst. S's.

University College Hospital, Gower-street, W.C.—Holiday Surg. Reg. £2 2s. weekly. Asst. Radiologist. £300.

Wakefield, Clayton Hospital.—H.S. £200.

West London Hospital, Hammersmith-road, W.—Hon. Med. Radiologist.

Whittingham County Mental Hospital, nr. Preston, Lancs.—Pathologist and Asst. M.O. £440 17s.

Wolverhampton and Staffordshire General Hospital.—Res. Cas. O. £250.

Worcester County and City Mental Hospital, Powick, near Worcester.—Jun. A.M.O. £300.

Births, Marriages, and Deaths.

BIRTHS.

MACDONALD.—On April 13th, at Walter-road, Swansea, the wife of William Macdonald, M.D., of a daughter.

MARRIAGES.

GILL—JOHNSON.—On April 11th, at St. Stephen's Church, Congleton, A. Wilson Gill, M.D., Chatterley Cottage, Hanley, Staffs, to Edith Mary, elder daughter of the late R. L. Johnson, Butterton Hall, Newcastle, Staffs, and Mrs. Johnson, Henshall Hall, Congleton, Cheshire.

KEANE—MURPHY.—On March 28th, at Malta, Major M. Keane, O.B.E., R.A.M.C., to Lulu Gordon Murphy, Q.A.I.M.N.S.

VERNEY—CONWAY.—On April 10th, at the Holy Innocents' Church, Fallowfield, Ernest Basil Verney, M.B., Ch.B., M.R.C.P., fourth son of Mr. and Mrs. Verney, of Tonbridge, and Ruth Eden Conway, M.B., Ch.B., M.R.C.P., eldest daughter of Professor and Mrs. Conway, Didsbury, Manchester.

DEATHS.

LATHAM.—On April 13th, at a nursing home, Arthur Carlyle Latham, M.D., F.R.C.P., of 11, Portland-place, last surviving son of P. W. Latham, M.D.

MOORE.—On April 9th, at the Shrubbery, Epsom, Stephen Henry Moore, F.R.C.S. Eng., aged 64 years.

St. JOHN.—On April 11th, at "Tregoeze," Eltham, S.E., Alexander Storey St. John, M.R.C.S., L.R.C.P.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

LOWESTOFT AND NORTH SUFFOLK HOSPITAL.—The hon. medical staff of this hospital, in their annual report for 1922, state that 453 patients were admitted during the year, of whom 282 recovered, 114 were relieved, and 12 were not relieved; 52 patients died, of these 10 within 24 hours of admission. There were 65 medical and 388 surgical cases treated during the year, and 248 operations were performed. The total number of attendances in the out-patient department was 4568, besides 570 minor casualties and 6386 daily dressings. There were also 254 minor operations, and 4540 attendances for massage and electrical treatment. The medical staff considered that the efficiency of the hospital was all that could be desired; it was managed by a painstaking subcommittee under an excellent chairman.

Notes, Comments, and Abstracts.

ON WATER-CRESS: ITS VALUE IN THE DIETARY.

WATER-CRESS (*Nasturtium officinale*) belongs to the same natural order (*Crucifera*) as cabbage, brussel sprouts, savoy, sea-kale, cauliflower, broccoli, borecole, turnips, radishes, mustard and cress, and horse-radish, many of which are now esteemed highly for their vitamin content. Raw cabbage leaves contain all three vitamins, and it is probable that water-cress also contains all three. Water-cress has the advantage of being consumed raw, while cabbage has a large percentage of its vitamins destroyed by cooking. So far water-cress has only been actually tested for vitamin C, but as it is a vegetable which can be grown all the year round and sold at a price within reach of all buyers, it would be interesting to learn whether it contains any of the other vitamins.

Water-cress in Ancient Times.

Mr. T. W. Sanders, editor of *Amateur Gardening*, gives us in "Vegetables and their Cultivation" (fourth edition, W. H. and L. Collingridge) some interesting information about water-cress. It has been cultivated from time immemorial. The ancient Greeks esteemed it highly as a food and a medicine. It was supposed to put life into dull and stupid persons. Hence their proverb "Eat cress and learn more wit." Xenophon advised the Persians to feed their children with it to increase their stature, just as MacCollum to-day, with a similar object, advocates more milk for Japanese children. In this respect Xenophon may be regarded as the forerunner of the vitamin school. Pliny recommended water-cress with vinegar as a remedy for deranged minds. The ancient Dutch ate it largely. In our country Gerard, at the end of the sixteenth century, said: "The eating of water-cresses restores the wonted bloom to the cheeks of young ladies," and Lord Bacon said: "Water-cress is an herb that while young is friendly to life." Dr. Arnold Lorand, of Carlsbad, in his book "Health and Longevity Through Rational Diet" (F. A. Davis Company, Philadelphia, 1912) says that water-cress has been used for ulcers of the mouth, from its property of stimulating the saliva. It "stimulates the appetite, and is often served with fine roasts." According to him it is digested most easily when taken in the form of a purée. It was in favour among the ancient Persians as well as the Greeks and Romans, both as a food and a medicine, and the name *Sanité du corps* was given to it by the French. It was first cultivated in Germany at Erfurt, was seen there by Cardon, an officer of Napoleon's army, and by him introduced into France. "In France," says Dr. Lorand, "it is eaten in considerable amounts at almost every meal; in Austria and Germany, on the other hand, it is used comparatively seldom." Dr. Lorand mentions the risk of enteric fever, if the water in which it is grown becomes specifically contaminated. He also says that it contains important substances, such as iodine and iron, and that it has been claimed to have a value in the treatment of many skin diseases, including stubborn cases of eczema, to have a favourable action in constipation, and to stimulate the appetite. In his Bradshaw lecture on "Sub-tropical Esculents" Dr. M. Grabham mentions that in the Atlantic Islands (Madeira, Canary, Cape Verde) water-cress grows in every mountain stream, and is largely used as an ingredient in Spanish and Portuguese soups, a "spinach" of water-cress containing the fungus *Boletus edulis* being in high esteem as a dainty. He says also that water-cress is held in repute locally as a remedy for various disorders.

Its Modern Cultivation.

Water-cress has thus in many lands and at many times had a high reputation as a health-promoting food. Although it is true that we do not spoil it by cooking it in this country, to many people it is simply a garnish or ornament to the dish of game or poultry, and removed by the waiter in the serving dish. There is many a patch of low-lying land in this country, worth merely a nominal rent, where water-cress could be profitably cultivated, if an increased demand arose for it. The possibility of its conveying the infection of enteric fever has been much reduced in recent years, and it would not be a difficult matter to protect water-cress beds. The county authorities responsible for the prevention of the pollution of rivers could add the supervision of water-cress farms to their present responsibilities, and the supply of an easily-grown, cheap, fresh food would probably create a larger demand, to the advantage of the community.

THE LANCET, Dec. 31st, 1921.

GRAUNT'S NOMENCLATURE OF DISEASE.

THAT the domestic therapeutists of the seventeenth century were responsible for some of the names of diseases which still puzzle the curious is indicated clearly by the work on vital statistics, originally written by John Graunt in 1665 and edited in 1676 by his friend, the great William Petty, the political economist. The book in question is "Natural and Political Observations mentioned in a following Index, and made upon the Bills of Mortality." Graunt was a Hampshire man, presumably of Inverness-shire origin, and was one of the earliest members of the Royal Society. Was he the Mr. "Grant" whom Pepys mentions once as a collector of topographical engravings? He was by trade a haberdasher, and held office as Captain of the "Trained Band." His calling, which was also Isaac Walton's, seems to have been commented on when the Royal Society was enduring the same kind of chaff as the British Association for the Advancement of Science underwent in the pages of "Pickwick" 90 years ago. Charles II., however, hoped that if there were more haberdashers like Mr. Graunt they would all be elected Fellows of the Royal Society, while Petty so thoroughly agreed with Graunt's investigations that he practically re-wrote Edition 5 of his book, sometimes speaking of it as his own—which led Evelyn to attribute it to Petty (*Diary*, March 5th, 1675)—and founding upon it that "Political Arithmetic," which became in time our Political Economy. Graunt was therefore an authority in his day, and his opinions on nomenclature deserve respect. But he was puzzled by such odd terms as "the Rising of the Lights" and "Stopping of the Stomach," though incidentally he tells us that "Livergrown" means the "Overgrowing of Children's Livers and Spleens (as by the Bills may appear)," and that "Tissick" is Phthisic phonetically spelt. "Chrisoms," according to Bailey's Dictionary, Edit. 8, 1737, are "Infants that die within the Month of Birth, or while they wear the Chrisom Cloth." Thirty-eight chrisoms died, it will be noted, in the year 1706, but to state that a baby died within a month of birth is not to tell us of what it was ill. And some such consideration leads Graunt into an amusing account of the method of death certification 250 years ago, from which it would appear that in every district a "Searcher" was appointed to look into the causes of death. These searchers were usually ancient women, prototypes of Mrs. Gamp or of those rich mines of Folklore, the old creatures who lay out the dead in country places even to-day. These searchers were perfunctory, nay cursory. "The Old-women Searchers after the mist of a Cup of Ale, and the bribe of a Two-groat fee, in stead of one given them," were wont to put down all emaciated corpses as consumption cases. We can imagine that they only peeped in at infectious cases like plague, and that they relied much on gossip and the theories of relatives. Hence their reports were very mixed, and they were apt to confound accidents with diseases, and the age-incidence of death ("infants," "chrisoms," &c.) with causes. On the other hand, they reflected, in their complete ignorance, popular views as to disease and queer fashions in nomenclature. Thus Graunt notes that "Rickets" began first to appear in the Bills in 1634. "Now the Question is, whether that Disease did first appear about that time; or whether a Disease, which had been long before, did then first receive its Name?" "There seems also," he continues, "to be another new Disease . . . The stopping of the stomach, first mentioned in the year 1636 . . . Forasmuch as the *Rickets*, *Stopping of the Stomach*, and *Rising of the Lights*, have all increased together, and in some kind of correspondent proportions; it seems to me that they depend one upon another, and that what is the *Rickets* in Children, may be the other in more grown Bodies; for surely Children, which recover of the *Rickets*, may retain somewhat to cause what I have imagined; but of this let the Learned Physicians consider, as I presume they have."

The learned have been of late years still considering "the Rising of the Lights" (see THE LANCET, 1913, i., 933, 1003, 1070, 1143). In old lists the full phrase is sometimes "Mother, or Rising of the Lights." "Mother," or uterus, refers to the theory that puerperal convulsions are the result of the lifting or rising up in the interior of the body of the womb. But Graunt is of opinion that the Rising of the Lights is a rising of the lungs. ("Lights" is still the butcher's word for lungs). "For I remembered that some Women, troubled with the Mother-fits, did complain of a *choaking in their Throats*. Now, as I understand, it is more conceivable, that the Lights or Lungs (which I have heard called The Bellows of the Body) not blowing, that is, neither venting out, nor taking in breath, might rather cause such a *Choking*, than that the *Mother* should rise up thither, and do it. For methinks, when a Woman is with Child, there is a greater rising, and yet no such Fits at all." Green-sickness and hysteria were often traced to this imaginary rising of the lights, as also was strangulation.

The stoppage of the stomach is, in the opinion of Graunt, probably due to constriction caused by rickets. The livergrown in infancy—rickety infants—becomes in later life

"stoppage in the stomach." He rejects the popular belief of many that it is due to an uprising of the *mother*. The term was probably used vaguely for a variety of illnesses, including stoppage of the bowel, but Graunt holds to the view that it was a specific disease.

Akin possibly to the above factitious diseases is "strongullion (or strongullion)." Strongullion appears first in the Bills of Mortality in 1701 and disappears completely from them in 1717. Neither Graunt, nor Dr. Johnson, who read Graunt, nor Bailey, nor "Nares's Glossary," nor the "New English Dictionary," nor any known medical dictionary makes mention of this word. It may have some connexion with *Strongylus*, a modern name for a species of tenia. In fact, *strongylus* may be a reminiscence of strongullion. The word *strongyla* occurs in Terentius Pallius for a bust (Greek *στρογγύλη*). The disease strongullion may therefore have been connected with the thorax. It is a learned term, not one due to the popular imagination of the "Searcher," but it remains a mystery.

THE PUBLIC SCHOOLS YEAR-BOOK.

THE 1923 edition of this year-book is the thirty-fourth to be issued. Since 1910 it has been the official book of reference of the Headmasters' Conference, and a prefatory summary of the work of the committee of the Conference is given, together with an abstract of the resolutions adopted at the last annual meeting of the Conference. The first part of the volume contains full details relating to about 140 schools; the second part is devoted to up-to-date information concerning entrance scholarships at public schools, entrance examination to universities, and conditions of admission to the Navy, Army, Air Force, Civil Service, and other professions. The concluding section contains lists of preparatory schools and other matters of general interest. The publishers are Messrs. H. F. W. Deane and Sons, The Year Book Press, 31, Museum-street, London, W.C. 1; the price is 10s. 6d.

THE INSTINCT OF FLIGHT.

IN his concluding paper on the Instinctive Factor in Hysteria in the *R.A.M.C. Journal* for March Major V. T. Carruthers (retired) shows how difficult it may be in the individual case to separate the conscious from the unconscious activities. The springs of action are obscure. They may be due to reflex action, to instinct, to intelligence, or to reason, and it is difficult to demarcate between the spheres of each. The disorder of function we know as hysteria, which is due to disorder of instinctive action, cannot always readily be distinguished from the disorder of reflex action which is disease, or from that misworking of intellect which is malingering. Until recently no instincts but the sexual were supposed to have much influence on human conduct, but that this was a mistake became very clearly apparent during the war, when it was seen that the self-regarding instincts (submission and display) and the instinct of flight were of great importance both as motives of human conduct and as causes of hysteria.

The instinct of flight is awakened when a man is put in fear; it should be overmastered by the intelligence, but physical exhaustion or over-stimulation may lessen the intellectual inhibition, and the behaviour that now results is due to instinct unrestrained. The decision may perhaps not be made by the higher centres at all, but lower down in the brain, the organism doing its best to save itself, as the omentum throws itself, without its owner's wish or knowledge, upon the intestinal damage when it is commencing, to ensure that the threatened harm is so far as possible prevented. These lower-brain decisions were often noted to be eminently prudent. The man who broke down in the front line rarely suffered from paralyses which would have prevented him from moving out of danger; he might develop mutism or anaesthesia. Paralyses of locomotion which would preclude return to the trenches took place well behind the front line. And just so, Major Carruthers might have added, shell shock was very rare in the navy in the war, and only occurred among men who were in action ashore. On board a ship in action shell shock was no help to a weak man; on the contrary, it would prevent him from helping himself if the ship should sink, and his instinct recognised it was safer to go on fighting.

The self-regarding instincts, Major Carruthers went on, are two, the instinct of display or self-assertion or pride, and the instinct of submission or subjection. Very often the patient who has been in some way injured in his self-esteem, and has had his subjection brought home to him, tries to rehabilitate his position by "going sick," and having doctors, nurses, and friends running after him; he is now, he feels, the centre of the picture, and his *amour propre* is for the moment satisfied. Self-abasement is more of an instinct to women. Hysteria of display not due to an antecedent depression is rarely severe, but does occur. Major Carruthers himself noticed that not a few officers

who went sick with functional nervous diseases were to a great extent impervious to shame, so it was not self-abasement followed by self-assertion that had brought on their hysteria, but the imperious instinct of flight, uninhibited by personality or education, and in time it became a blot on a man's record if he had shell shock.

These papers, with their discussion of instinct in insects and other animals, and their exposition of this biological theory of hysteria and its links with those of Babinski, Janet, and Freud will repay study as a whole.

NEO-MALTHUSIAN CONFERENCE REPORT.

THE report of the Fifth International Neo-Malthusian and Birth Control Conference, held at the Kingsway Hall, London, from July 11th to 14th, 1922, has been published in book form by Mr. Heinemann. The meeting of the contraceptive section, open to members of the medical profession, was fully reported in THE LANCET of July 22nd, 1922. Readers who are interested in birth control, from whatever standpoint, may be glad to find set out in one volume not only reports from foreign countries but a collection of addresses on various aspects of the subject by those who have given them close study.

THE YEAR-BOOK OF SCIENTIFIC AND LEARNED SOCIETIES.

WE have received from Messrs. Charles Griffin and Co. the thirty-ninth annual issue of the Year-book of the Scientific and Learned Societies of Great Britain and Ireland. This is a record, compiled from official sources, of the work done during the session 1921-22 by numerous societies and government institutions in the regions of science, literature, and art. It is divided up into 14 sections dealing respectively with (1) science generally; (2) astronomy, mathematics, and physics; (3) chemistry and photography; (4) geography, biology, and mineralogy; (5) biology including microscopy and anthropology; (6) economic science and statistics; (7) mechanical science and architecture; (8) naval and military science; (9) agriculture and horticulture; (10) law; (11) literature, history, and music; (12) psychology; (13) archaeology; (14) medicine. In each case the information given includes the names of executive officers, times of holding meetings, the conditions of membership, and a list of papers read during the past session. Reference to the index shows how large is the number of societies included, and we gather from the preface that the few which have been discontinued are more than counterbalanced in number by the new societies dealt with. The section of medicine is comprehensive, although naturally not exhaustive, and the chief value of the year-book will doubtless be found by those who desire information outside the range of their own particular professional connexion. The year-book is one of that type of publication which becomes more valuable from year to year, and the present issue is conspicuous for its high degree of accuracy and comprehensiveness.

SUPERANNUATION AND LIFE ASSURANCE IN INDUSTRY.

THE information department of the Industrial Welfare Society has drawn up a number of instructive and suggestive notes¹ as to the formation of pension funds for superannuated workers, by the combined contributions of employers and employed. Life assurance and "group assurance" are also touched upon in the memorandum. Many such schemes as are dealt with exist already, for we have travelled far since the early days of last century, when the worker was exploited and his health sacrificed for the benefit of the capitalist who paid him a starvation wage and left him to his fate when his working life was over. Superannuation schemes are no doubt a heavy charge upon industry and indirectly upon the consumer of its products. The high contributions necessary are explained as due to better conditions of employment, sanitary and otherwise, which have caused a longevity in industrial workers, previously unknown, and in view of which provision for longer enjoyment of pensions must be made. The importance of the movement will be realised if we reflect upon the part played by food and living conditions in the upbringing and maintaining of a healthy race, and upon the desirability of preventing the lapse of the worker into squalid poverty when his vigour has declined. His condition, whether of poverty or of comparative security, affects not only himself but any young persons dependent upon him, and freedom from anxiety as to his future must have its influence upon his health and capacity for work during his service. The memorandum of the Industrial Welfare Society should prove a valuable guide to those who are seeking to amend and improve existing organisations.

¹Memorandum on Superannuation and Life Assurance Schemes, Prepared by the Industrial Welfare Society, 51, Palace-street, Westminster, S.W. 1.

Three Lectures

ON THE

CULTIVATION OF TISSUES AND TUMOURS IN VITRO.

Delivered at University College, London.

BY A. H. DREW, D.Sc.,
IMPERIAL CANCER RESEARCH FUND.
(With Illustrative Plates.)

LECTURE II.*

(Delivered on March 7th, 1923.)

In the last lecture I dealt with the preparation of the various reagents necessary for successful tissue culture. It is now necessary that we should consider some of the characters of normal tissues growing outside the body. Just as in bacteriology an immense increase in knowledge was gained when a satisfactory technique was devised for preparing pure cultures, so in a detailed study of tissues and tumours it is highly desirable to be able to deal with pure cultures of cells. Three chief methods may be used in dealing with this problem, which may be considered under the following headings: mechanical separation, separation by ultra-violet light, and separation by encouraging the growth of one type of cell at the expense of others.

MECHANICAL SEPARATION.

This process is due to Carrel, and consists of growing a culture in a plasma medium and selecting portions of the growth which appear to be free from mixture with other cells when examined with the microscope; these portions are then carefully excised with iridectomy knives and are transplanted to fresh medium. With care and experience this method yields good results with plasma cultures, but is not very successful with cultures made in the saline medium.

SEPARATION BY ULTRA-VIOLET LIGHT.

This is probably the best means of separation for cultures in the saline medium, as after a few failures pure cultures can be readily obtained. A series of cultures of the selected tissue, say, kidney, are put up and examined daily till vigorous growth takes place. In one or more of any series of cultures pure kidney cells will be found growing free from connective tissue elements in certain portions of the growth. A minute globule of mercury is then carefully pushed on to the preparation and so arranged as to cover the selected cells. Provided the globule is not too large it will be found to remain in position fairly well. The slide is then removed from the microscope and placed under a mercury-vapour lamp, care being taken that it does not become heated. After an exposure of from five to ten minutes it is removed, fresh culture medium added, and the slide returned to the incubator. On examination it will be found that the cells unshielded by the mercury have been killed and growth is taking place from the small fragment of culture shielded and is pure in character. With care the same technique may be applied to plasma cultures, but here it frequently fails. It is best to grow the primary cultures intended for this separation on quartz cover-glasses.

SEPARATION BY SELECTION.

If cultures of heart be incubated at a rather high temperature, 40° C. for a few hours, the heart cells gradually die off, and a pure culture of connective tissue is obtained; the same holds for certain tumours and other tissues. As a rule this procedure cannot be recommended, as it often fails to effect a separation. Its chief merit is the ease with which it is done and the saving of time secured. Pure cultures, having been obtained, merely require

frequent subculture to maintain growth indefinitely. As a matter of routine, subculture should be carried out every three days, as then the cells are kept in a state of maximum activity. Although when dealing with normal tissues frequent subculture is advantageous, yet it is not necessary to the same extent as is found to be the case when growing tumours. Cultures of actively pulsating heart have been left for as long a period as 13 days before subculture, and beating has continued throughout the whole period. Cultures may also be obtained from tissues removed aseptically and stored in the cold; for example, we have obtained good active growths of kidney after 18 days storage in the ice-chest. Examination of young actively growing cultures shows that growth is normal in all respects; the mitotic figures are quite normal and the chromosomes can frequently be counted. The mitochondria are unaltered unless the tissue is beginning to require subculture, when they may be found to be forming fat. Cultures of mamma from a pregnant animal will continue to form fat droplets which will render the culture fluid very milky. Such a phenomenon does not occur with ordinary mamma cultures.

Epithelium grown in pure culture occurs as a sheet of undifferentiated tissue. A pure culture of myoblasts growing as a sheet may show active pulsation. Figs. 1, 2, 3, and 4 illustrate pure cultures of heart, kidney, skin, and mammary gland respectively. Although cultures when pure grow as undifferentiated sheets, differentiation may be induced by the addition of cultures of connective tissue. Fig. 5 shows a pure culture of kidney epithelium. If to such a pure culture a portion of connective tissue is added, differentiation sets in, usually within 48 hours, and rudimentary tubule formation takes place. This is well shown in Fig. 6, which illustrates a portion of the culture from Fig. 5 subsequently grown with connective tissue. When we come to consider tumour growth, exactly the same thing will be found to occur. The correct dosage of connective tissue to produce this result is largely a matter of chance. If too much be added the connective tissue outgrows the kidney and ultimately replaces it; if, on the other hand, too little be added, the kidney may fail to react and ultimately overgrows the connective tissue. The same type of phenomenon is seen in skin cultures, which when pure tend to grow as a sheet of somewhat spindle-shaped cells, but in the presence of connective tissue show signs of commencing keratinisation. Fig. 7 illustrates the type of growth so obtained. When working with the saline medium and adult tissues, the best method of obtaining satisfactory cultures, is to use rather larger pieces of tissue than is customary with embryos, and to subculture—i.e., to renew the culture fluid daily, whether growth takes place or not. If a sufficiently large number of cultures be put up and treated in this manner a proportion of them will be found to show slight traces of growth in from 8 to 14 days. Once initial growth has been obtained it may be easily maintained by repeated subculture. It must be clearly borne in mind, however, that for the continued culture of cells the medium, whether plasmatic or saline, must contain fresh embryo extract. As Carrel has pointed out, cultures without such extracts fail.

ADULT AND EMBRYONIC GROWTHS.

Adult and embryonic tissues growing in the saline medium exhibit a striking difference. While growth is practically immediate in embryonic tissues, adult tissues always show a very long lag; this point is brought out by the accompanying chart:—

Growth of Embryonic Tissue in Ordinary Saline Medium
+ Embryo Extract.

++ +++ ++++ +++++ 4 days.

Growth of Adult Tissue in Ordinary Saline Medium + Embryo Extract.

0 0 0 0 0 0 0 0 0 0 0 0 + + + 13 days.

The reason for this curious lag shown by all adult tissues will shortly become apparent. From a

R

* Lecture I. appeared in THE LANCET of April 21st.

consideration of the phenomena of repair, it seemed likely that substances given off by damaged cells would act as a stimulus to cell proliferation, and these experiments appear to indicate the truth of this surmise. If tissues such as kidney, spleen, or liver be finely minced, mixed with an equal volume of the saline medium, incubated at 30° C. for two or three hours, and then centrifuged, the supernatant fluid is found to contain a substance, or substances, capable of accelerating the growth of adult tissues very greatly. As has already been stated, adult tissues when grown in a saline medium exhibit a very long period of lag during which no growth takes place whatever. If, however, an adult tissue be put up in culture in the saline medium containing some of the extract above described, it is found that vigorous growth will take place within a period of from 24-48 hours. Growth of this nature having once been obtained, if subcultured into a similar medium—that is, into a medium still containing an autolysed extract—instead of continuance of the growth, early degeneration with ultimate death of the whole culture takes place. If, however, after the initial period of growth such a culture be subcultured into the ordinary medium without an autolysed tissue extract, growth is maintained steadily without degeneration setting in, and may be kept going for an indefinite period, just as with cultures of embryonic tissues. Such growth obtained in this manner appears to be perfectly normal. The mitoses observed differ in no way from those observed in ordinary actively-growing cultures of either embryonic or adult tissue made in the usual manner. We have here an explanation of the period of lag observed in cultures of adult tissues. During the lag period many of the cells would appear to die out, and only when the concentration of the products of autolysis becomes sufficient to initiate cell proliferation do we find growth commencing. Whatever the nature of this substance is, it does not appear to be of the same nature as embryonic extract, as although it has been found that embryonic extracts suffer greatly in their efficiency when exposed to heat at 60° C. for 15 minutes, this amount of heat has been found totally inadequate to affect in any way the potency of such autolysed extracts of adult tissues. If extracts of adult tissues are made, the tissues being kept ice-cold, the saline medium also being cooled, and the mixture centrifuged at once without being allowed to undergo autolysis, such an extract is found to be inert and to cause no stimulation of growth in cultures. It is, therefore, clear that whatever these substances may be, they are only evolved during the process of autolysis, and therefore take some time to appear in the medium. This fact should be borne in mind, as when we come to consider tumour growth in our next lecture it will assume a very important aspect.¹

LECTURE III.

(Delivered on March 17th, 1923.)

WE have in this last lecture to consider some of the points regarding tumour growth outside the body, and to contrast it with the growth of both adult and embryonic tissues. The earlier workers on the subject found that tumours were more difficult

¹ Points dealing with the differentiation of tissues and growth with autolysed extract (Lecture II.) and the whole of Lecture III. have been much abridged, as they are being fully dealt with in a forthcoming paper in the *British Journal of Experimental Pathology*.

to grow and maintain in subculture than were embryonic tissues, and this is still found to be the case, the tumours generally occupying an intermediate position between the embryonic and adult tissues. The great difficulty in tumour culture is to maintain growth in successive subculture and to prevent the tumour becoming overgrown by connective tissue. As an example of the kind of difficulty one meets with, we may take a rapidly-growing sarcoma, No. 37 S of these laboratories. If such a tumour be cultured into a plasma-embryo extract, medium growth occurs in 24 hours, the plasma is liquefied, and one obtains a ring-shaped growth shown in Figs. 8 and 9. Small portions of the growth may break away from the main fragment, and these also grow as typical ring cultures; these are well seen in Fig. 9 representing a single culture in which two small fragments have broken away from the main portion and are seen growing as separate rings. If such a plasma culture be examined daily, it will be found that degeneration is setting in on the second day, and in a few days the culture dies out. I have shown that this is due to substances liberated from the tumour cells, and that the degeneration may be overcome by daily subculture into fresh medium. When this is done growth takes place as a sheet of spindle-shaped cells which may be kept growing indefinitely. Fig. 10 represents a portion of a pure culture of No. 37 sarcoma. Such cultures inoculated into mice reproduce the same type of tumour as that from which they were originally grown. Fig. 11 illustrates some of the figures obtained from tumour cultures.

PURE CULTURES.

It is just as necessary to obtain pure cultures of tumour cells as it is to obtain normal cells in a like condition, and the same technique is adopted. Many tumours, and notably the carcinomata, show a tendency to grow out at first as finger-shaped processes of pure tumour cells; these can easily be either cut off or covered with mercury and exposed to ultraviolet light in the manner already described. Fig. 12 shows a mouse carcinoma growing in this manner. When such a tumour is obtained in pure culture, growth takes place as an undifferentiated sheet of tissue similar to that shown in Fig. 13.

Just as we have seen that differentiation may take place in pure cultures of embryonic cells when growing with connective tissue, so the same thing is found to occur with tumours. For example, we see that in Fig. 6 a pure culture of mouse carcinoma grows as a sheet of undifferentiated tissue. If to such a pure culture connective tissue be added, growth occurs in the form of acini, and the whole culture strongly resembles normal mouse mamma. Fig. 14 illustrates this type of differentiated growth. Figs. 15 and 16 show the same thing. To a culture of heart containing connective tissue a fragment of a pure culture of a carcinoma was added. It will be seen how the carcinoma cells invade the heart tissue, and as they come into contact with the connective tissue, acini are beginning to be formed. Fig. 16 illustrates a portion of the growth under a higher power. The delicate balance between connective tissue cells and tumour cells is soon lost with continuous growth, and ultimately one type of cell overgrows the other; usually the connective tissue grows more rapidly, and ultimately it is again obtained in pure culture.

We have already seen that autolysed tissue extracts had a remarkable effect on adult tissue growth; such

an effect is well shown by the accompanying chart, which illustrates the growth of adult tissues in ordinary saline media and in media with an autolysed extract added.

Tumour cells in such a medium are adversely affected. A rapidly-growing tumour shows very early degeneration, while slower-growing tumours appear to be stimulated to faster growth, but here again early degeneration sets in very rapidly. It can be shown that tumours spontaneously liberate some substance or substances similar to those formed during tissue damage, for a fresh extract prepared from tumours in the cold contains a very potent growth-stimulating substance for adult tissues. Fig. 17 shows an 11-day growth of adult rat kidney in an ordinary saline medium plus embryonic extract. It will be seen that only a minimal trace of

it must be borne in mind that the culture here is only 48 hours old, compared to the 11 days' growth of the other. The growth obtained by the aid of such extracts is frequently of an explosive character—that is to say, growth may occur all around the original fragment, and portions becoming detached grow about on the slide in all directions; such a type of growth being illustrated in Fig. 19.

FIG. 19.

THE HÆMORRHAGES OF THE NEW-BORN.*

By JOHN NORMAN CRUICKSHANK, M.C.,
M.B., Ch.B., F.R.F.P.S. GLASG.,

PATHOLOGIST TO THE GLASGOW ROYAL MATERNITY AND WOMEN'S HOSPITAL; SENIOR ASSISTANT TO THE MUIRHEAD PROFESSOR OF MEDICINE, UNIVERSITY OF GLASGOW; DISPENSARY PHYSICIAN, GLASGOW ROYAL INFIRMARY.

(Working on behalf of the Medical Research Council.)

THE varieties of hæmorrhage which are found in the new-born form a subject which is of some importance in the study of the factors which lead to death of the foetus before and during birth and of the infant in the first few days of life. In the first place two perfectly distinct forms of hæmorrhage are to be differentiated.

1. The so-called "hæmorrhagic diathesis of the new-born"—a convenient if somewhat inaccurate term which includes several varieties of hæmorrhage of known and unknown origin.

2. The important group of true birth hæmorrhages—with which, chiefly, the paper deals.

The subject of hæmorrhage in the new-born is one to which a good deal of attention has been drawn recently, but it is by no means a new one. Scattered through the medical literature of the past 30 years and more one finds references to it. There is often evidence of complete confusion between the various forms of bleeding met with, and their relative frequency and importance have seldom been sufficiently emphasised. It may, therefore, be of interest to present the subject briefly, and to refer to some of the results of the work which is being carried out in the Research Department of the Glasgow Royal Maternity and Women's Hospital on behalf of the Medical Research Council.

1. The Hæmorrhagic Diathesis of the New-born.

All the varieties of hæmorrhage which are included for convenience in this group are of rare occurrence. Only a few cases have come under my observation, and I therefore deal with this aspect of the subject briefly. On the one hand they are to be distinguished from the true birth hæmorrhages, and on the other from hæmophilia. All three types of hæmorrhage are quite distinct in ætiology. In 1891 Townsend read a communication before the Boston Medical Society in which the term "hæmorrhagic disease of the new-born" was applied to a condition in which small or large effusions of blood occur in various parts of the body—apparently spontaneously. He pointed out the transitory nature of the illness, and in discussing its ætiology was inclined to favour an infective origin. He was probably the first observer to make a clear differentiation between such spontaneous hæmorrhages and the asphyxial and traumatic hæmorrhages of birth. The commonest manifestations of these spontaneous hæmorrhages, which are grouped together under the name "the hæmorrhagic diathesis," are bleeding from the gastro-intestinal tract, bleeding into the skin, bleeding from the umbilical cord, and late bleeding into the suprarenals and other viscera. If space permitted one might also mention some of the less common forms of the diathesis, such as the curious epidemic form of hæmoglobinuria described by Bigelow and others. There is, undoubtedly, a group of hæmorrhagic conditions which are definitely associated with sepsis in one form or another. From the accounts in the older literature it would appear that at one time this type of bleeding was very much more frequent than it is nowadays. This is not surprising in view of the comparative infrequency of sepsis generally with the employment of modern aseptic methods. There is also a group of cases in which hæmorrhage appears to be dependent on the presence of syphilis. An interesting account of this condition was published in 1904 by Hless of Chicago. There are still other cases in which no cause can be

found. Possibly a certain number of these are really atypical cases of true birth hæmorrhage.

2. The Hæmorrhages of Birth.

Entirely separate from the various forms of spontaneous hæmorrhage, which have been mentioned under the general term hæmorrhagic diathesis, there is a large group of hæmorrhages which are associated with the congestion and asphyxia of birth. It is these hæmorrhages which form the main theme of the present communication. They are of surprisingly frequent occurrence, and the question of their prevention forms a difficult problem which, till recently, has not been given the consideration which it merits. The extent and variety of these hæmorrhages, though seldom sufficiently emphasised, is really no new discovery. A very complete demonstration of the commoner lesions was given by Herbert Spencer in a communication published in 1892, and it is interesting to compare his findings with the almost identical results of more recent observations. That the incidence of these forms of hæmorrhage should have remained almost unchanged suggests that the improvements in obstetrical technique which have been introduced in the past 30 years or so can have had little effect on the factors which are responsible for the production of these lesions. Without attempting to explain completely the ætiology of the hæmorrhages of birth one may perhaps try to demonstrate in a general way the mechanism by which they are produced.

(a) Prenatal, Intranatal, and Neonatal Asphyxia.

The foetus in utero is in a state of apnoea. How exactly respiration is established is still largely a matter of conjecture, but the following theoretical explanation is pretty generally accepted. Though somewhat incomplete, it seems on the whole reasonable. In the course of normal delivery the O_2 and CO_2 tension are so balanced in the foetal blood that there is sufficient oxygen to meet the needs of the tissues between the time of cessation of the placental respiratory exchange and the establishment of pulmonary respiration, while at the same time the tension of CO_2 remains sufficiently low to prevent stimulation of the respiratory centre till the child is born. It is probable, though actual proof is still lacking, that the tension of CO_2 required to stimulate the respiratory centre during foetal life is very much higher than that reached at any time under normal conditions when there is no interference with the placental circulation. Feldman, in speaking of this aspect of the physiology of the neonatal period, accepts as most probable the theory elaborated by Schwartz, according to whom the foetal respiratory centre becomes more and more irritable in the later months of pregnancy as a result of the increased vascosity of the blood which reaches the medulla owing to the gradual narrowing of the ductus arteriosus. A condition of partial asphyxia is thus produced, and during labour it is increased by the interruption of the placental respiratory exchange. The foetus thus passes from a state of apnoea to one of dyspnoea, and the respiratory centre is stimulated not only by the increased CO_2 tension of the blood, but also by reflex stimuli from the skin so that pulmonary respiration becomes established. If these theoretical explanations are correct, the child at birth is in a state of partial asphyxia which deepens until the respiratory centre is sufficiently excited by the increased CO_2 tension and by cutaneous stimuli. We do not know what relation the variations in oxygen tension may have to the establishment of pulmonary respiration in the foetus at birth, but in view of the most recent work on the physiology of the respiration it seems unlikely that this factor can be ignored.

It may be accepted that a certain degree of asphyxia is normally present before and during birth. Obviously any circumstance which leads to an undue lengthening of the interval between the cutting off of the placental respiration and the establishment of the pulmonary respiration must increase this degree of asphyxia to a point beyond the physiological limit. Whether the interruption of placental exchange of gases be caused by premature separation of the placenta or by delay

* A paper read before the Southern Medical Society, Glasgow.

in the birth of the child and in the establishment of independent respiration, the result is the same. From birth onwards the normal respiratory centre responds to increased CO_2 tension in the blood in such a way that the respirations become deeper and more frequent, and the partial pressure of alveolar CO_2 is prevented from increasing beyond the normal limit. Such a mechanism is, of course, impossible in the fœtus in utero or during parturition.

With regard to the production of neonatal asphyxia, there are two main factors which suggest themselves. The first is the observation that while a moderate increase of CO_2 will stimulate the respiratory centre, an excess will ultimately paralyse it. The second factor is that the respiratory centre may have its activity diminished by interference with its blood-supply. In a series of experiments, quoted in Luciani's text-book of physiology, Kusmaul and Tenner showed that a gradual arrest of the cerebral circulation will so exhaust the respiratory centre that marked dyspnoea appears. When the cerebral circulation is restored, however, there results a period of apnoea which they explain on the grounds that the normal CO_2 tension of the blood is not sufficient to stimulate the exhausted respiratory centre. It is suggested that the first of these factors may be involved in the failure to initiate respiration in many asphyxiated infants, while the second factor may be responsible for those cases in which there has been interference with the fœtal circulation during birth from pressure. In the production of prenatal and intranatal asphyxia another factor is occlusion of the umbilical vessels either from twisting of the cord round fetal parts or from prolapse of the cord during labour. Here, again, either or both of the above-mentioned mechanisms may be in action.

The pressure of the contracting uterine walls is, undoubtedly, an important element in deepening asphyxia and increasing congestion, and it is probably responsible for the production of many of the hæmorrhages to which reference will be made presently. That severe asphyxia may develop in utero from interference with the placental respiratory exchange before labour has commenced at all can be demonstrated in cases of maternal death from accidental hæmorrhage in which no labour pains have occurred. As the degree of asphyxia deepens the circulation becomes more and more embarrassed and congestion appears throughout the body. The heart continues to act and the congestion becomes more marked. If no relief is obtained, the congestion becomes so great that certain of the smaller vessels give way and petechiæ and capillary oozings appear in various situations. There may even be gross hæmorrhage into the viscera. All these effects may be produced by the asphyxial congestion alone, quite apart from the additional trauma of labour. This is shown in the cases of concealed accidental hæmorrhage just mentioned. When, however, there are added to this extreme congestion the force of strong uterine contractions and the pressure of the passages to which the child must be moulded, the risk of gross hæmorrhage is enormously increased. It is not surprising to find, then, that in a very large number of cases such hæmorrhages do exist.

(b) Traumatic Hæmorrhages (Intranatal).

In addition to the hæmorrhages which arise as described from extreme congestion alone, there are various types of bleeding which are produced by trauma superimposed on asphyxial congestion. To this class belong most of the grosser forms of intracranial and visceral hæmorrhage. Such trauma may be due either to pressure of the maternal parts or to obstetrical interference. The importance of asphyxial congestion as a predisposing cause of these hæmorrhages was pointed out by Ashby in 1890. Spencer, on the other hand, was inclined to lay more stress on trauma as the main factor in their ætiology. From our findings at the Maternity Hospital one has the impression that the presence of asphyxial congestion is the essential element in the production of hæmorrhage,

that the increase of this congestion by the pressure of the maternal passages is the next most important element, while injuries due to abnormalities of presentation or to operative interference occupy the third, though still one of the important places in the ætiology of these lesions.

It is in the production of severe intracranial hæmorrhage and the grosser forms of visceral hæmorrhage that intranatal injury shows its greatest effect. The work of Holland, and later that of F. J. Browne, has drawn attention to the frequency of injuries to the dural septa—particularly the tentorium cerebelli. Such dural tears are in many cases the cause of gross fatal intracranial hæmorrhage. While this incidence has not been so great in the cases examined by Prof. A. M. Kennedy and myself in Glasgow as in those examined in London and Edinburgh, their frequency is still sufficient to make them rank among the important lesions associated with birth. To the same category belong many of the cases of gross hæmorrhage into internal organs and rupture of the capsule of the liver with intraperitoneal bleeding.

Results.

Having thus briefly outlined the mechanism by which the hæmorrhages of birth are produced, one may now consider the results of these processes—the actual lesions found in the new-born. These results are based upon an investigation of 200 mature infants and 200 premature infants, which was carried out by Prof. Kennedy and the present writer.

Hæmorrhages (see Table I.).

Mature Infants.—In the series of 200 mature infants hæmorrhage of greater or less degree was present in 154 cases—a percentage incidence of 77. If allowance be made for certain craniotomy cases, the incidence rate of hæmorrhage in this group of 200 mature infants becomes approximately 80 per cent.

TABLE I.—Incidence of the Various Grades of Hæmorrhage in 200 Mature and 200 Premature Infants.

Lesion.	Mature.	Premature.
	Per cent.	Per cent.
Hæmorrhage—all grades	80	66.5
Capillary oozings or petechiæ only	30	26.5
Gross hæmorrhage	50	40
Gross intracranial hæmorrhage	32	22.5
Gross intracranial hæmorrhage and visceral hæmorrhage	10	12.5
Visceral hæmorrhage without intracranial hæmorrhage	13	13
Intracranial hæmorrhage alone	22	15
No hæmorrhage	20	33.5
Tentorial tears	30	12

In 55 instances, however, the hæmorrhage consisted of capillary oozings or petechiæ only, and if these be neglected, there was gross hæmorrhage in 99 cases—approximately 50 per cent. of the series. There were 65 cases—about a third of the series—which showed meningeal hæmorrhage of a gross character. In 44 of these cases meningeal hæmorrhage was the only gross hæmorrhage present—though capillary oozings or petechiæ were noted in most instances—while in the remaining 21 cases the meningeal hæmorrhage was associated with gross hæmorrhage into the viscera. In 34 cases—approximately one-sixth of the whole series—there was hæmorrhage into the viscera without meningeal hæmorrhage. This group contained eight cases of craniotomy, however, so that it would be more correctly estimated at 26—an eighth of the series.

Premature Infants.—Two hundred premature infants which were born during the eighth or ninth lunar months of pregnancy were examined, and it was found that in 133 cases hæmorrhage was present. This is an incidence of 66.5 per cent. over the whole series of 200 cases, and the correction necessary to allow for the inclusion of craniotomy cases is here negligible. In 52 of the premature infants the bleeding did not amount to more than capillary oozings or petechiæ, so that there was gross hæmor-

rhage in 81 cases—approximately 40 per cent. of the whole. Meningeal hæmorrhage, apart from other gross bleeding, was found in 30 cases, and in 25 cases there was meningeal hæmorrhage associated with hæmorrhage into the viscera (approximately one-fifth and one-eighth of the series respectively). In another eighth of the cases—26 to be exact—there was gross visceral hæmorrhage without meningeal hæmorrhage. The inclusion of two cases of craniotomy in this group makes little difference to the figures.

Comment.

In comparing the incidence of hæmorrhage in the group of mature cases with that in the group of premature cases the most striking difference is that, while only 20 per cent. of the mature infants were free from hæmorrhage, practically 35 per cent. of the premature infants had escaped. The percentage incidence of most of the types of hæmorrhage is lower in the premature group than in the mature group by a fairly constant amount; but the incidence of meningeal hæmorrhage was the same in both.

Tentorial Injuries (see Table I.).

The incidence of tentorial tears was practically the same in the two groups—9.5 per cent. of the mature infants and 10.5 per cent. of the premature infants showing complete or incomplete rupture of this structure. These figures are low compared with the findings of other workers, but they may be explained in part at least by the presence of a large number of cases of craniotomy in the series. Thus, in the group of 200 mature infants there were 20.5 per cent. of craniotomies, while in the premature group there were 2.5 per cent. of craniotomies. Most of these were "failed forceps," and presumably the majority would have shown tentorial injuries had the head not been destroyed at operation. It seems permissible to add the greater number of these craniotomy cases to the group showing tentorial tears. If this be done, the incidence of tentorial tears becomes approximately 30 per cent. in the mature group and 12 per cent. in the premature group. This is equivalent to 24 per cent. of the total 400 mature and premature cases.

With regard to the factors leading to the occurrence of these ruptures of the tentorium, it is to be noted that in 79 per cent. of the mature infants showing such injuries the labour was abnormally long, and in 9 per cent. it was precipitate. Among the premature infants no cases of precipitate labour were associated with tentorial injuries, but 90 per cent. of the cases of tentorial tearing in the group had been delivered after a protracted labour. Contracted pelvis was present in the mothers of seven (about one-third) of the mature infants, and in two (about one-tenth) of the premature infants showing tentorial tears. Antepartum hæmorrhage had occurred in four (about one-fifth) of the mature cases and in 11 (about one-half) of the premature cases. Version had been performed in three (about one-seventh) of the mature cases and in eight (about two-fifths) of the premature cases. In six (about one-third) of the mature cases and in four (about one-fifth) of the premature cases there had been a forceps delivery. With regard to the presentation, it was found that in 47 per cent. of the mature cases and in 52 per cent. of the premature cases the child was delivered by the breech. This high proportion of breech cases demonstrates the risks of tentorial injuries which are associated with the comparatively rapid delivery of the aftercoming head. Only one transverse presentation occurred in each group.

The effect of such injuries in causing intranatal death is demonstrated by the fact that 84 per cent. of the mature infants and 66 per cent. of the premature infants showing tentorial tears were still-born, while of those which survived birth only one lived more than a day or so.

Comment on the Two Series of Cases.

From the examination of these two series of cases it is evident that the two main types of lesion can be distinguished. The commonest, hæmorrhage, occurs

in about 70 per cent. of all the cases, and is distinctly more common in the mature foetus (80 per cent.) than in the premature foetus (66.5 per cent.). The other type of lesion, intracranial injury, occurs much less frequently, being found in not more than 20 per cent. of cases. Like the hæmorrhages, this type of lesion shows a greater incidence in the mature than in the premature foetus.

Hæmorrhages.—With regard to the ætiology of hæmorrhage, the factor of greatest importance appears to be the passive congestion which is produced by prenatal and intranatal asphyxia. Postnatal asphyxia plays a part in a small number of cases only. The degree of congestion depends, chiefly, on the length of time which elapses between the interruption of the interchange of gases in the placenta and the establishment of pulmonary respiration. Sometimes the birth occurs so rapidly that the child is in a state of apnoea, while in other cases the delay is such that the child is asphyxiated to a greater or less degree. It may be born before the asphyxia proves fatal, or it may die from the effects of asphyxia before delivery. That visceral or other hæmorrhages may occur from asphyxia alone is confirmed by the finding of such lesions in several foetuses which were delivered at post mortem. In these cases the mother had died from the effects of concealed accidental hæmorrhage before any uterine contractions had taken place. The placenta was separated from the uterine wall by the hæmorrhage, gaseous interchange had thus been interrupted, and the foetus had died from asphyxia with all the usual evidence of extreme congestion and petechial hæmorrhages.

That these asphyxial hæmorrhages may be supplemented or increased in amount by pressure of the parturient canal during labour is obvious. Hæmorrhages due to such pressure really fall into the category of birth injuries, however.

From the finding of hæmorrhages in infants which had died during the first few days of life from bronchopneumonia or some other condition it is clear that at least the lesser degrees of birth hæmorrhage are not necessarily fatal. What effect, if any, they produce on the subsequent health and development of the child is a question beyond the scope of the present study.

Tentorial Injuries.—The factors leading to the production of tentorial lesions are more complex than those which give rise to birth hæmorrhages. The alterations in the diameters of the head, which occur during its passage through the parturient canal, form the basis of their ætiology. The size of the head in relation to that of the pelvis, the degree of ossification in the cranial bones, the length of the labour, and, above all, the presentation and the performance of operative measures, are all concerned in the causation of tentorial injury. In the present series it will be noted that a large proportion of the infants showing tentorial tears were delivered by the breech. This fact tends to confirm the prevalent opinion that the aftercoming head is particularly prone to suffer lesions of the dural structure during its comparatively rapid delivery. The influence of operative measures—particularly of version—is shown by the number of premature infants with tentorial tears whose delivery had been so complicated.

Incidence of Still-birth in Mature and Premature Infants (see Table II.).

In the series of 200 mature infants 90 per cent. were still-born in the group which showed capillary oozings and petechiæ only, 77 per cent. were still-born in the group showing meningeal hæmorrhage alone, 76 per cent. were still-born in the group showing meningeal hæmorrhage associated with visceral hæmorrhage, 59 per cent. were still-born in the group showing visceral hæmorrhage without meningeal hæmorrhage, and 54 per cent. were still-born in the group in which no hæmorrhages were found.

In the series of 200 premature infants (eighth and ninth lunar months) 65 per cent. were still-born in the group showing capillary oozings and petechiæ only

TABLE II.—Incidence of Still-birth in Relation to the Various Grades of Haemorrhage in 200 Mature and 200 Premature Infants.

Lesion.	Mature.	Premature.
	Per cent.	Per cent.
Capillary oozing or petechiae	90	65
Intracranial haemorrhage alone .. .	77	56
Intracranial and visceral haemorrhage ..	76	56
Visceral haemorrhage alone .. .	59	76
No haemorrhage .. .	54	43
Tentorial tears .. .	84	66

56 per cent. were still-born in the group showing meningeal haemorrhage alone, 56 per cent. were still-born in the group showing meningeal haemorrhage associated with visceral haemorrhage, 76 per cent. were still-born in the group showing visceral haemorrhage without meningeal haemorrhage, and 43 per cent. were still-born in the group in which no haemorrhages were found.

Comment.

The incidence of still-birth in the various groups of mature and premature infants shows several interesting features. In the first place there is the difference of 25 per cent. in the rate for cases showing capillary oozings and petechiae only. The next is the very similar variation—20 per cent.—in the rate for cases showing meningeal haemorrhage alone. The third, and perhaps the most striking point, is the 20 per cent. excess of still-births in the premature infants with meningeal and visceral haemorrhages over the still-births in the corresponding group of mature infants. It may be noted in this connexion that while in 22 mature infants with meningeal and visceral haemorrhages there were five cases of antepartum haemorrhage (23 per cent.), there were 14 cases of antepartum haemorrhage (56 per cent.) in the group of 25 premature infants which showed meningeal and visceral haemorrhages.

From the examination of such figures as the above it is evident that many infants with quite extensive birth haemorrhages are born alive and survive. In a number of the cases investigated death had occurred from some quite independent condition such as broncho-pneumonia or nephritis, and it is probable that, but for the intervention of such a disease, the child might have survived beyond the period of infancy with which one is particularly concerned.

ROYAL EASTBOURNE EYE HOSPITAL.—This institution was established in 1913 and was first known as the Eye Infirmary, but in 1921 it changed its name to Eye Hospital and is now known as the Royal Eastbourne Eye Hospital. The annual report submitted to the subscribers on April 10th showed that the new patients numbered 993, an increase of 145 on 1921. The purchase of the freehold of the hospital premises was completed during the year; the property was free from debt, and the building and the equipment had been valued at £3200 odd. The cost of maintenance had increased from £590 to £768, but despite this, last year's deficit had been liquidated and £70 was carried forward.

TUBERCULOSIS OF THE SACRO-ILIAC JOINT.*

BY H. C. WARDLEWORTH NUTTALL,

F.R.C.S. ENG.

HONORARY SURGEON, BOOTLE BOROUGH HOSPITAL; HONORARY ASSISTANT SURGEON, ROYAL SOUTHERN HOSPITAL, LIVERPOOL.

AT a recent clinical meeting I had the honour of exhibiting a patient upon whom I had performed a resection of the sacro-iliac joint for tuberculosis. I propose now to give the results of a survey of the literature of the subject, and the records of nine cases, for eight of which I am indebted to Prof. Thelwall Thomas, who also kindly assisted me in obtaining some of the literature; the remaining case is my own.

It is just over a century since the tuberculous nature of some cases of sacro-iliac disease was first recognised. Between 1821 and 1879 numerous papers were published, but the majority of surgeons considered operation inadvisable. It was not until 1889, when Mayo Collier's paper appeared, that the question of operation was reconsidered and began to find favour. Collier's paper was closely followed by others from Makins and Golding-Bird, all three surgeons giving accounts of cases treated by trephining and scraping with fair results. These three papers form the basis of the treatment given in most surgical text-books at the present day. That this treatment is inadequate I shall endeavour to show by what follows. As in other surgical problems, an accurate knowledge of anatomy and pathology paves the way for an appreciation of the significance of the symptoms and signs, and is essential to correct diagnosis and logical treatment.

Working on these lines, Bardenheuer, in 1899, described a method of resection of the joint by means of a Gigli saw introduced within the pelvis and cutting from within outwards. Bardenheuer's method errs on the side of severity, since it is by no means always necessary to perform such a radical operation, and it is not easy to adapt it to the varying conditions which may be present. The latter provision is fulfilled by the method described by Picqué in 1909, the principle of which is the removal of the portion of the ilium overlapping the joint, and the methodical following up of the disease, as far as may be necessary, from without inwards. After careful study, Picqué's method appeared to me to be based on sound principles, and I adopted it for my patient. I shall give the details of technique later, but first it is desirable to consider briefly the chief facts in the anatomy and pathology of the joint. Only thus are we prepared to understand the reasons for the failures in the past and the hope of success by more radical treatment in the future.

Anatomy.

The sacro-iliac joint can no longer be regarded as a synchondrosis and is now generally admitted to be an arthrodial or gliding type of diarthrosis. The auricular-shaped surfaces on the ilium and sacrum are covered by two plates of cartilage, of which the sacral is considerably thicker than the iliac. Between the two plates is a narrow cleft, provided with a synovial membrane; the size of this cleft varies at different ages, and it may be partially or completely obliterated by fibrous bands passing between the cartilaginous plates. It is the occurrence of this latter condition which has caused the joint to be described as a synchondrosis. The exact position and extent of the iliac auricular facet should be carefully noted (Fig. 1). It occupies, roughly, the lower third of the posterior or sacral part of the inner surface of the ilium below the tuberosity. Anteriorly it curves upwards as far as the middle of this surface, and posteriorly it extends to the posterior border of the ilium on the inner surface of the postero-inferior spine. The bone at the anterior part of the facet is

* A paper read before the Liverpool Medical Institution.

fully one inch thick. The auricular facet on the sacrum, according to Fawcett, is ossified from costal epiphyses which appear about the eighteenth year, and after fusing together, unite with the diaphysis at the twenty-fifth year. The iliac facet is formed by the diaphysis. The pathological significance of this will appear later. Owing to the wedge shape of the sacrum, the ilium overlaps it very considerably posteriorly and makes the joint difficult of access.

The ligaments may be divided into two groups, capsular and accessory. The capsular ligaments are conventionally described as the superior, inferior, anterior, and posterior sacro-iliac, together with an interosseous ligament, which is intimately connected with the posterior sacro-iliac. These ligaments are blended together around the joint to form the capsule, but they are chiefly concentrated at the posterior aspect, where they occupy the deep crevasse between the bones. They effectually shut in the joint posteriorly and prevent the spread of pus backwards. The accessory ligaments are the great and small sacro-sciatic, the sacro-lumbar, and the ilio-lumbar, to which may be added the lumbar aponeurosis, the tendon of the erector spinæ, and the fascia lata. Surgically their importance lies in their wide attachment to the lumbar vertebræ, sacrum, and ilium, thus preventing excessive movement at the joint and providing a stout pelvic brace after extensive resection of bone.

The movements permitted are only small in extent, but they are increased when laxity of the ligaments has occurred in pregnancy. They consist in a gliding up and down, and forwards and backwards, together with a slight rotation on a transverse axis, which permits a rocking movement of the sacrum, the promontory passing forwards, the apex backwards, and vice versa. The fact that movement is permitted at the joint renders it more liable to sprain, the so-called relaxation. Apart from movement, the joint is subject to the varying pressure and strain of the weight of the trunk as it is transmitted, via the joint, to the innominate bones and lower limbs. Whereas the function of most joints is active, to permit extensive movement of one part of the body in relation to another part the function of this joint is entirely passive, and is concerned in the absorption of shocks and the easing of strains.

We should expect, therefore, to find what is actually the case, that no muscles act directly on the joint. Indirectly it is affected by the contraction of the muscles of the abdomen, pelvis, back, and thighs. In disease of the joint the action of these muscles causes pain, and conversely they are liable to spasm in an endeavour to fix the joint.

The nerve-supply is important, since the localisation of pain in disease of the joint is very variable, and is to be accounted for by the wide distribution of the nerves which supply the joint, or are in close relation to it. It is supplied by the superior gluteal, and twigs from the anterior and posterior primary divisions of the first and second sacral nerves. The lumbo-sacral cord and the obturator nerve are related to it anteriorly. The nerve roots concerned include the second to the fifth lumbar and the first two sacral—practically all the roots concerned in the formation of the lumbo-sacral plexus. The intimate relations are, above, the psoas and iliacus; below, the pyriformis, superior gluteal nerve, and gluteal vessels; posteriorly, the dense ligaments and the erector spinæ; anteriorly, the internal iliac vessels, the lumbo-sacral cord, and the obturator nerve; externally, the ilium covered by the glutei; internally, the upper sacral foramina and the sacral nerve roots. These structures are largely concerned in determining the position of an abscess and its spread in various directions.

Pathology.

With regard to the pathology, the disease is rare compared with tuberculosis of the spine or hip, and particularly so in children. The age-incidence of the cases I have studied falls between 20 and 30, and there were four males and five females.

The primary focus is invariably in the bone, either sacrum or ilium, the former being the more common. According to some, primary infection of the ilium does not occur, and this is the more likely since, as pointed out above, there is no secondary centre for the iliac facet. A primary synovial infection has never been recorded. Tuberculous caries ensues, the bone becoming softened and eroded; extension to the joint follows sooner or later, and the other bone is then attacked. Necrosis frequently occurs, and sequestra are common. More or less sclerosis may be present in the immediately surrounding bone. Continuation of the carious process results in the breaking down of the tissues to form an abscess, which gradually increases in size and follows the line of least resistance. This is determined by the anatomical relations of the joint already considered. Intrapelvic abscess is commoner therefore than extrapelvic, and the pus may follow the psoas sheath downwards into the thigh or upwards into the iliac fossa or lumbar region; or it may pass into the thigh, via the lumbo-sacral cord and great sciatic nerve or obturator nerve and vessels. The superior gluteal nerve and gluteal vessels conduct the pus to the buttocks; and in other cases it has passed between the obturator and anal fascia to the ischio-rectal fossa, and has even entered the rectum, bladder, or vagina. Extrapelvic abscesses point directly in the buttock, but often possess several loculi amongst the glutei.

Eventually, in neglected cases, the abscess bursts on the surface; secondary infection follows and the patient's life is made miserable by the presence of a sinus discharging pus. These sinuses may be very tortuous and of great length; moreover, the walls vary greatly in consistence according to whether they pass through soft tissues or bones and ligaments. Drainage through them is poor; they therefore tend to be multiple, and their presence materially increases the difficulties of treatment. A fatal termination follows upon the diffusion of the abscesses and general infection.

Symptoms and Signs.

The history of onset is variable; there is often a history of injury or sprain. In one case an influenzal attack immediately preceded the joint symptoms; in other cases either a swelling or limp may be the first sign, and pain may be absent; more frequently the initial symptom is pain, usually associated with weakness of the limb and more or less limp on walking. The character and site of the pain are very variable; it may be a localised aching or a radiating stabbing pain, felt in hip or knee, lower part of the back, buttock, or back, or inner side of the thigh, according to the nerve-twigs affected. It is usually worse at night, and is increased by any movement of the joint or neighbouring structures—e.g., sitting, standing, walking, or jarring the heel; coughing, sneezing, defæcation, or micturition; compression or separation of the iliac spines, hyperflexion, or hyperextension of the trunk or thigh. In conjunction with the pain the patient limps, only short steps being taken with the affected limb, and the weight being kept as far as possible on the sound side. As a further consequence of this a slight scoliosis may be present. In some cases, owing to relaxation of the ligaments, the patient complains of a peculiar feeling of weakness, as if the pelvis were falling to pieces, especially on defæcation or other abdominal strain. Tenderness on direct pressure over the joint is a valuable sign; this is best elicited by pressure over the postero-inferior iliac spine, where, as already noted, the joint closely approaches the surface.

Reflex muscle spasm follows in due course in an endeavour to fix the joint. The immediate effects of this may be to cause further pain owing to irritation of the sciatic nerve by the ischial head of the biceps; or deformity, such as flexion of the hip or lordosis, from spasm of the psoas. The latter condition may also be due to direct irritation of the muscle. Later this spasm leads to atrophy of the muscles, most obvious in the flattening of the buttock and loss of the

gluteal fold. In about three and a half months from the onset, on an average, a fluctuating swelling appears in one or other area, as outlined in discussing the pathology. It may or may not be tender on palpation and there may be an impulse on coughing.

Diagnosis.

The difficulties of diagnosis are to be accounted for in several ways, and at the outset I may say that there is no sign pathognomonic of this disease. Compression of the ilia is frequently painless when extensive disease is present; on the other hand, it gives rise to pain in primary disease of the acetabulum. The prominence given to this sign is therefore unjustified. Mistakes in diagnosis appear to be due in the first place to inefficient examination. It cannot be too strongly emphasised that in the examination of a patient complaining of persistent pain in the back, or sciatica, the practitioner is not giving himself a fair chance unless the patient is stripped so as to expose the whole of the back and legs. It is only by a careful routine examination of the spine, pelvis, and lower limbs, together with rectal and vaginal examinations, that mistakes in diagnosis are to be avoided. Moreover, the protean character of the symptoms and signs confuses the mind, and secondary effects are apt to be taken for primary lesions. Lastly, the undoubted rarity of the disease, and the inconspicuous nature of the functions of the joint, lead to the condition being entirely forgotten, especially as more common diseases are so frequently simulated.

In the early stage, before abscess formation, the most reliable sign is the presence of tenderness on direct pressure over the joint. Patients frequently complain of pain over the joint in sciatic neuritis or other conditions, but as a rule true tenderness is absent. In discussing the pathology, it has been seen that the infection is primarily in the bone, and one would expect that a radiogram would show some change in the shadow. This must depend on destructive bone changes, which probably take one or two months to develop. X ray examination, therefore, is a valuable confirmatory test, and should be repeated after an interval in a suspected case. The other symptoms and signs are commonly present in other diseases, and appear more likely to mislead than to aid in diagnosis. In the later stage after the formation of an abscess, the presence of a fluctuating swelling, together with the tenderness over the joint, and the X ray appearances, renders the diagnosis a simpler matter. The abscess may point, however, at a considerable distance from the joint.

The question of differential diagnosis is so extensive that it is impossible to discuss it adequately in the time at my disposal. I can only briefly allude, as follows, to some of the more important conditions which may give rise to difficulty.

First, other diseases of the joint. It must be remembered that it is subject to the same lesions which occur in other joints. Of these the acute infections (pyogenic or gonorrhœal), osteo-arthritis, and sprain are the most important. The chief distinguishing characters are the acute onset, pyrexia, and more rapid course of the infective conditions, the likelihood of other joints being affected, the history, and the X ray appearances. Clinically it is impossible to distinguish between early tuberculosis and sacro-iliac sprain or relaxation, but the latter speedily recovers with rest and strapping of the pelvis; the radiogram is negative.

Secondly, affections of the neighbouring bones and joints, such as tuberculosis of the hip or spine, scoliosis, chronic sprain of the back, sarcoma of ilium or sacrum, and malformation of the fifth lumbar transverse process, may be excluded by careful examination and the radiographic appearances. For instance, in hip disease limitation of movement is quite definite in all directions; in sacro-iliac disease gentle examination shows that movement at the hip-joint is painless in one or other direction. The same remark applies to the spine. A radiogram will show growths of the

bones or periostitis of the fifth lumbar transverse process in cases where it impinges on the crest of the ilium.

Thirdly, affections of nerves; true sciatic neuritis is distinguished by the tenderness of the nerve trunk and the absence of tenderness over the joint. This requires careful demonstration, since the chief tenderness of the nerve is sometimes at the lower part of the great sacro-sciatic foramen, a site fairly close to the lower part of the joint. Muscular atrophy may be present in either condition, but anæsthesia points to neuritis. The nerve may be involved in sacro-iliac disease, in which case tenderness is present over the joint and nerve, and the other joint signs are also present. Tumours of the cauda equina give rise to pain, and later anæsthesia, in the distribution of the posterior roots, and atrophy of muscles supplied by anterior roots. At first unilateral, this closely simulates sacro-iliac disease, but the atrophy of muscles occurs earlier, tenderness is not localised to the joint, and the anæsthesia is against it. Moreover, lumbar puncture may show presence of albumin and fibrinogen in the cerebro-spinal fluid.

Lastly, other affections, such as growths in the pelvis, ovarian or uterine disease, or appendicitis may give rise to pain about the joint, but should be excluded by the routine examination. I must confess that I am somewhat sceptical as to the difficulty of diagnosis in some of these conditions, but Rugh mentions two cases of appendicitis simulating sacro-iliac disease, in one of which a competent surgeon curetted the joint!

Prognosis.

The prognosis in the past was invariably bad, and, judging from the records, it is not greatly improved by limited methods of trephining and scraping. This is only to be expected from the anatomical and pathological evidence already considered. On the other hand, this forms the clearest indication for more radical methods, and the records of cases thus treated are very encouraging. It is very difficult, however, to arrive at a clear conclusion as to the value of a method of treatment in a small series of cases. The rarity of the disease precludes the possibility of impressive statistics, and we must form the best judgment we can from the evidence available.

Of Mr. Thelwall Thomas's eight cases, between 1905 and 1916, an abscess was present in all except one. Two cases were not operated upon; one of these had no abscess and was cured by rest, the other was a boy of 15 whose abscess burst spontaneously. Of the six cases operated upon, five were incised and scraped; three of these were discharged with sinuses present, in the other two the condition on discharge is not stated. In the sixth case the joint was excised and the patient was discharged cured. I have only been able to trace three of these cases. One is the boy, whose sinus is now healed, the other two were cases which were incised and scraped, and discharged with sinuses present; one of these died two months later, the other is now in Fazakerley Hospital, confined to bed with five sinuses. We may take it that, in Mr. Thomas's hands, these results are as good as anyone would have obtained by the less radical methods. For our present purpose it is significant that a cure followed in the only case where excision was performed.

Turning to the results of the more radical methods. Picqué records five cures in seven cases. My patient, aged 31, had a large extrapelvic abscess and a sequestrum was present; the operation was performed in September, 1921. At the present time he shows no sign of local recurrence, has gained over a stone in weight, is able to walk without a limp, and follows his previous occupation.

Treatment.

Coming now to the question of treatment, enough has been said to show that the old method of trephining and scraping is not sufficiently radical, since it does not permit of complete removal of all the diseased bone, and gives at best a very poor and imperfect

approach to the more common intrapelvic abscess. I very much question the permanent value, in cases where an abscess is present, of the bone-graft operations described by some American surgeons, with a view to fixing the joint, and shall not discuss them here. Nor can I here discuss the ethics of conservative treatment, beyond saying that I should give it a trial in children.

Picqué's Method.

I shall now pass to the details of Picqué's method, which is based on the following principles: (1) an approach to the joint by cutting away the posterior overlapping portion of the ilium; (2) the resection of more or less of the sacrum, as may be necessary, to the complete evacuation of any intrapelvic abscess; (3) the methodical following up of the disease by means of the gouge or curette, so that a smooth granulating surface may be formed without pockets or sinuses.

Technique.—This is as follows. The incision is curved (Fig. 2), passing along the posterior third of

cut away depends on the extent of the disease, and varies from a simple curetting, or a superficial chipping by the gouge, to an extensive resection of the lateral portion of the sacrum.

This method of approach permits of bone being cut away precisely from the neighbourhood of the nerve roots with little danger of injury. On the other hand, if the curette is relied upon with insufficient exposure, nerve injury is only too probable. Moreover, an intrapelvic abscess can be completely evacuated and explored, due regard being paid to the important structures in relation to the anterior surface of the joint. The bony walls of the cavity are now made as smooth and regular as possible, avoiding depressions and pockets which favour retention of discharges. The whole area is swabbed with bipp, and the wound packed with gauze soaked in iodoform emulsion; the ends of these packs are brought out at the middle of the incision and the remainder sutured. During the next 48 hours fresh dressings are applied, as required, over the original one, which is not disturbed.

FIG. 1.

Auricular facet superimposed upon outer surface of ilium.

FIG. 2.

Reflection of flap and line of section of ilium.

FIG. 3.

Portion of ilium resected; sacral surface of joint exposed.

the iliac crest and downwards on to the lateral edge of the sacrum. The knife cuts down to the bone at once and the whole flap is raised from the dorsum ilii, by a periosteum elevator, until the upper border of the great sciatic notch is exposed, with the superior gluteal nerve and gluteal vessels coming out of the pelvis below it. The structures attached to the iliac crest are also freed by the elevator. As the flap is turned down any superficial abscess is dealt with by the curette. In using this instrument my ideal is to remove the tuberculous granulation tissue without penetrating any fibrous wall that may have formed beneath it. If time is to be saved, it should not be at the expense of this part of the operation, for I am sure that it is most important to get away all tuberculous material if possible. An inspection of the bone and ligaments usually reveals the track by which the pus has travelled backwards. Picqué figures a partial and a complete section of the ilium, the former limited to the upper half or two-thirds of the posterior part of the ilium, the latter including the whole of the posterior part, from the iliac crest to the great sciatic notch. A reference to Fig. 1, in which the auricular facet is superimposed upon the outer surface of the bone, shows that the partial operation leaves the greater part of the joint behind, and for that reason I think the section should always pass into the notch (Fig. 2).

The bone is gradually cut through by chisel or osteotome, commencing at the iliac crest about 3 inches from the postero-superior spine, downwards to the junction of the upper and anterior borders of the notch. Finally the portion to be excised is levered up and removed by cutting the ligamentous fibres attached to it. The sacral surface of the joint is now exposed (Fig. 3), and any sequestrum present may be removed. The amount of bone now requiring to be

The packs are then removed under gas anaesthesia and the suturing of the wound completed. After this extensive operation a considerable amount of oozing occurs which is checked by the packs, when they are removed firm pressure over wool prevents further hæmorrhage.

The patient is kept in bed with the pelvis firmly bandaged for four or five weeks, at the end of which time a pelvic belt is fitted and he is allowed up on crutches. The crutches may be discarded in a favourable case at the end of the twelfth week, but a pelvic belt should be worn until the patient feels that he can get along without it. One might expect much interference with the statics of the pelvis as a result of this resection of bone, but clinical experience shows that this is not the case, even where partial resection of the sacrum has been performed. A large mass of callus is thrown out by the bone and periosteum and the whole area is welded into a fibro-osseous mass, which is sufficiently firm to bear weight although a certain amount of torsion of the pelvis may be present.

Notes of Author's Case.

The following are the notes of my case:—

Male, aged 31. In August, 1920, he suffered from "sciatica" in the left thigh and lay in bed with severe pain for six weeks. When he got up the leg felt weak and powerless, and he supported himself on two sticks when walking. By August, 1921, a swelling the size of an egg had developed in left buttock; no pain until that month, when he felt a sharp pain shoot through the swelling, which was also getting larger. There had been a definite loss of weight.

Condition on Admission.—He was admitted to Bootle Borough Hospital on Sept. 5th, 1921. Painless fluctuating swelling in left buttock, ill-defined margin, about the size of an orange. Side pressure on pelvis does not cause pain. Tenderness on pressure over postero-inferior iliac spine. No tenderness of sciatic nerve; some pain on full flexion

or extension of left hip-joint; nil per rectum: spine and hip-joint normal; chest normal. Radiogram shows blurring of outline of left sacro-iliac joint.

Operation.—On the 9th incision along posterior third of iliac crest and along sacrum to third external tubercle; glutei, periosteum, &c., raised from bone and great sacro-sciatic ligament, two superficial abscesses being opened en route: further abscess found in midst of gluteus medius. All these abscesses carefully scraped. Suspicious point at upper end of great sacro-sciatic ligament proved to be a sinus leading to sacro-iliac joint. With osteotome, posterior portion of ilium chiselled through into great sciatic notch and portion of bone elevated and removed, exposing joint, sacral surface of which was necrosed and formed a sequestrum. No intrapelvic abscess present. Sacrum gouged and curetted, whole area bipped and packed with iodoform emulsion gauze. Superior and inferior portions of wound sutured and packs brought out at middle. Sample of pus sent to pathologist. Some collapse following operation, but patient recovered with salines, &c. Fresh dressings applied over original.

On the 10th a fairly good night, more dressings applied and salines continued. On the 11th I removed packs and sutured wound under gas. On the 14th Prof. J. M. Beattie, City of Liverpool Bacteriological Department, reported *B. tuberculosis* present in pus. On the 24th wound quite healed except two small areas which were granulating. No sign of any residual abscess. General condition good. On Oct. 4th left leg put up in a Thomas hip-splint, pelvic belt applied. On the 13th walking short distances with crutches. On the 15th discharged. On the 22nd returned for inspection; walking well with crutches, wound quite sound. On Dec. 3rd walking without crutches.

In August, 1922, patient was thrown out of a pony-cart on to his back, but beyond a contusion over the buttock he sustained no harm. He still wears a pelvic belt, has gained over a stone in weight, and continues his previous occupation.

Conclusion.

We may fairly conclude, then, from the foregoing, that the old operations of trephining and scraping are not based on a sound conception of the anatomy and pathology of the joint; that the results of these methods are poor as shown by the records of cases, and that much better results are to be expected from more radical treatment.

OPEN ETHER FOR THE OCCASIONAL ANÆSTHETIST.

By ARTHUR WATERS, D.M. OXF.,

HONORARY PHYSICIAN, RADCLIFFE INFIRMARY, OXFORD.

SOME mystery still seems to cling to the administration of "open ether," the safest and easiest anæsthetic for patient and administrator alike; I therefore venture—as one fairly often called upon to give anæsthetics, but not as a professed anæsthetist—to describe the simple apparatus I use and the method I adopt. Many a country practitioner resorts to the more dangerous drug chloroform, because he has never learnt to use open ether and because he finds his "Clover's inhaler" hors de combat when he unearths it after a prolonged rest.

Apparatus.

First, my apparatus is home-made, with the exception of a good "drop-bottle" which, in an emergency, can be readily improvised out of a small medicine bottle, a rubber cork, and a piece of glass tubing.

The following items are needed: (1) A piece of thick white felt¹ (it can be obtained $\frac{3}{8}$ in. thick),

¹ The thick white felt can be obtained from Messrs. Maw, Son and Sons, 7, Aldersgate-street, London, E.C.

measuring 10 in. by 6 in.; (2) a duster or a small towel; (3) a circular piece of ordinary white lint about a foot in diameter. The sheet of felt is folded round into a cylinder and the edges carefully sewn together by a double row of stitches, the inner edges first, the outer edges last. The sewing stops at a point about three-quarters of an inch from the bottom, and the square corners are rounded off. The notch so formed fits comfortably over the patient's nose. At the opposite end the sewing is continued to the very top. The piece of lint is next to be used to form an accurately fitting and perfectly flat diaphragm across the cylinder about an inch or an inch and a half from the top. The centre point of the circular piece of lint is pushed down about three inches into the cylinder from the top, the edges uniformly arranged around the circumference, slightly pleated, and securely and evenly stitched to the top edge of the felt. The lint being now securely fixed, it is flattened out with the fingers and a further row of stitches carried round through felt and lint lower down. Thus a flat diaphragm across the cylinder is formed. The edge of the lint is allowed to hang down outside all round. This completes the mask.

Technique.

Before use, the mask and small towel (folded like a scarf) are placed in a bowl of very hot water for about ten minutes and kept hot. Two ounces of pure ether are next poured into the drop-bottle.

As a routine in most cases I like my patients (except small children) to have a hypodermic injection consisting of 1/12 gr. heroin and 1/100 gr. atropin half an hour before the operation. It usually makes them pleasantly drowsy and allays nervousness. After examining the heart, &c., and with a few reassuring words, I thoroughly grease the patient's chin, lips, nose, and cheeks with vaseline, explaining the reason. Next I take the mask from the hot water, wring it out with my hand and place it lightly over mouth and nose. Breathing the moist warm air is quite pleasant, and as a preliminary a few drops of eau-de-Cologne or tincture of orange may be sprinkled on the mask. I next place two or three wisps of dry cotton-wool on the diaphragm and drop on to them a few drops of ether, telling the patient that I am beginning to give him ether and urging him to breathe quite naturally. Very quickly he tolerates a more rapid flow of drops from the bottle and as the wisps of cotton-wool on the diaphragm become saturated a few more may be added. The stream of drops should be continuous and directed in turn over each segment of the diaphragm.

When the patient begins to show signs of losing consciousness, the little towel folded in the shape of a scarf is wrung out, put under the chin and held by the left hand up against the mask, the ends are brought round the mask on either side of the face, obliterating any space between mask and skin through which too much air may be drawn in. The notch will fit the nose accurately and eyes and forehead are absolutely bare and easy of inspection. As unconsciousness deepens the ether may be dropped more quickly, and, in an average case, it will be found that when two ounces have been used the patient is just "under" and ready for the preliminaries of the operation. When full anæsthesia is established it is permissible to place an extra wisp or two of cotton-wool on the diaphragm, use a little more ether, and cover the top of the mask with a small sheet of wool or fold over the edges of the lint, whereby the patient for a short time gets less air and a stronger ether vapour. It is useful to be able to do this while you refill your drop-bottle, or in case you may want to deepen anæsthesia quickly. At the same time it must be remembered—as was pointed out to me by a leading anæsthetist during the war—that the most essential point in giving open ether is that the drug should be administered constantly, uniformly, and continuously.

Advantages of the Method.

I think that the following advantages can be claimed for this modification of the old "ether cone" method:

1. An efficient apparatus can be made in half an hour.
2. The mask being damp and warm at the start, the inhaled vapour tends to irritate the mucous membranes to a minimum degree.

3. The patient's forehead and eyes are uncovered and easy of inspection.

4. "Going under" is infinitely less disagreeable to the patient than in the method which one so often sees adopted in which the whole face is covered with cotton-wool and a low mask upon which ether is slopped promiscuously.

The felt masks are best cleansed by careful washing, followed by a soak in 1 in 40 carbolic. Too much boiling causes them to shrink very rapidly and to become hard. In any case they shrink after a certain amount of use, and so one is provided with smaller sizes for children.

A CASE OF PERSISTENT JAUNDICE IN AN INFANT.

By BERNARD MYERS, C.M.G., M.D. EDIN.,
M.R.C.P. LOND.,

PHYSICIAN TO THE ROYAL WATERLOO HOSPITAL, LONDON.

THE following case of persistent jaundice in an infant, with atresia of the common bile-duct and biliary cirrhosis of the liver, is of interest.

An infant, 7 weeks old, was sent to the Royal Waterloo Hospital by Dr. I. Outram, of Edmonton, being admitted on July 7th, 1922. The complaint was persistent jaundice, which had commenced two days after birth, becoming more intense during the second week and had persisted since. The motions were whitish. The urine was very distinctly bile-coloured. The child had been taking its food (breast-milk and Glaxo) well, and so far had enjoyed good health.

Condition on Examination.—The child showed no malformation, was seen to be fairly well nourished and markedly jaundiced on skin and conjunctivæ. The urine was distinctly bile-coloured and the faeces looked whitish or clay-coloured. The infant's napkins showed bile-staining. The liver was considerably enlarged, the lower border being over two inches below the costal margin. The spleen was not definitely palpable. Gentle pressure in the right hypochondrial region evidently caused pain, which was no longer noted after about a week. Weight of child, 8 lb. 4 oz. Nothing abnormal found in the chest. The mother stated that there is no similar case in her family, although her three other children had suffered from icterus neonatorum which disappeared in four or five days. She had had no miscarriages.

On the 11th there was a clinical note to the effect that there had been continuous vomiting since admission but the child had taken its food well. The icterus was still as marked as previously; there was no pyrexia. The child gained weight until the 14th, but on the 21st a loss of 8 oz. since admission was noted, and the child was not looking so well. The child continued to lose weight, and on August 14th the general condition was distinctly worse. The lower border of the liver was no longer palpable. The child died on the 23rd, aged 14 weeks.

The jaundice varied slightly during the last two weeks, but always remained fairly marked, being especially conspicuous on the conjunctivæ. The infant was fed on milk-mixtures which were altered to suit the circumstances when weight began to be lost, but no change of diet prevented further loss. The temperature varied from 96° to 98.4° F., and the pulse from 100 to 145, being mostly about 120. The bowels acted from two to three times daily as a rule, but sometimes there were four to five motions in 24 hours. No hæmorrhages in the skin or mucous membranes were noted at any time since birth.

The provisional diagnosis made during life was "absence, or atresia, of the bile-ducts." Although some tenderness existed and a little resistance was

felt in the region of the gall-bladder nothing definite could be made out at any time, and the tenderness disappeared during the last two weeks of life. There were no signs of syphilis. The Wassermann reaction was negative.

Necropsy.—At the necropsy, which was made by my house physician, Dr. Bruce White, within 24 hours of death, nothing abnormal was found in the lungs, heart, intestinal tract, stomach, glands, or serous cavities, although all the tissues were bile-stained. No hæmorrhages were seen. The liver was small and almost completely hidden under the costal arch. It was very dark green in appearance and indented on the surface in a manner suggesting cirrhosis. The gall-bladder was represented by a thin structure about one-fourth the ordinary size.

The liver and portions of the gastro-hepatic omentum, stomach, pancreas, and duodenum were removed together, placed in Kaiserling's solution, and sent to Dr. T. H. G. Shore, curator of the Museum, St. Bartholomew's Hospital, for an opinion. His report stated:—

"The liver is firm and of a dark-green colour. The anterior margin is sharp. The surface is smooth, but somewhat tuberculated, raised areas being separated from one another by linear depressions which have a branching arrangement, and are doubtless due to the close relation some of the portal spaces have to the surface of the liver. After a short preservation in Kaiserling's solution the weight of the liver is 152 g., which is probably not materially different from its weight in the fresh state. Anatomically the lobes of the liver are natural. The gall-bladder is small, cylindrical, and thin-walled, and contained a small quantity of dark-green bile. The hepatic ducts are not distended. The openings of the gall-bladder into the cystic duct, and of this into the common bile-duct are demonstrable, but the lumen of the common duct gradually tapers until it can be traced no longer, and the duct is lost in a mass of toughish fibrous tissue half an inch or more from what should be its termination. The portal vein and hepatic artery are easily dissected and are normal. The small portion of the pancreas left attached to the specimen contains the duct of Wirsung, which can be traced to a papilla on the mucous membrane of the duodenum situated about one and a half inches from the pyloric sphincter. This doubtless represents the ampulla of Vater. No other duct joins that from the pancreas at this point. The pancreas presents a normal appearance, except for some staining with bile pigment, a condition shared also by the duodenum.

Microscopic examination of the liver shows distension of the biliary radicles within the lobules. These small ducts contain plugs of dark-green material, and in places the adjacent liver tissue is stained in a similar manner. Some of the liver cells are small, and their nuclear staining is poor, but on the whole the cells are well preserved. The portal spaces are prominent; the bile ductules are distended and contain the same dark-green material as the bile capillaries; the arteries are thickened by an increase of the tissue of their middle coats, and the branches of the portal vein are similarly affected. The connective tissue of the portal spaces is increased in amount, and is markedly fibrous. Such thickened portal spaces can be seen lying at the bottom of fissures from the surface, as described above. Fibrosis is limited to the neighbourhood of the portal spaces."

Remarks.

Rolleston,¹ writing of this condition, states that the cirrhosis of the liver is first (probably) and cholangitis and obstruction of the ducts secondary and later results. Holmes² is of opinion, however, that it is usually a developmental anomaly and not the result primarily of inflammatory processes. He does not think that congenital obliteration of the larger bile-ducts is an extremely rare condition. A good number of cases have now been reported. Holmes quotes Benecke to the effect that in the 74 cases recorded by him the constriction or atresia occurred at the level of the papilla of Vater in the great majority of cases. Thomson³ states that of 67 cases 41 were males and 26 females. Rolleston¹ further remarks that "the spleen is usually enlarged, sometimes very greatly." (In this case it was never definitely enlarged.) "The jaundice may be present at birth . . . in some

² American Journal Diseases of Children, 1916, xi., 405.

³ Clinical Study and Treatment of Sick Children, 1921, Oliver and Boyd.

instances the infant is not jaundiced until two to three weeks after birth. When once established the jaundice is progressive. There is never much itching. The meconium is usually normal and rarely devoid of bile. The motions are usually clay-coloured from the first. Constipation is the rule; in a few instances diarrhoea is noted." (In the present case the bowels were always freely open.) Haemorrhages from the mucous membranes, into the skin, and from the umbilicus occur in a large number of cases. (No haemorrhages were noted in this case.) Infants usually waste if life is sufficiently prolonged (see above). Thomson³ observes that "no case in which the diagnosis was confirmed post mortem has survived the first year."

As regards treatment, Holmes² states that the child's nutrition must be maintained by administra-

tion, if necessary, of bile or bile-salts. With regard to surgical treatment, my colleague, Mr. J. A. Cairns Forsyth, remarks: "Since the outlook without operation is hopeless, exploratory laparotomy is justified on the off-chance that the obstruction may be low down in the common duct and anastomosis feasible. Unfortunately, only in about 16 per cent. of cases are the gall-bladder, cystic, and hepatic ducts pervious to the flow of bile. In addition, the patients are bad subjects for surgical interference on account of their tender age and the grave risk of haemorrhage. Failures have been common and successes few."

The liver from this case was shown at the Section for the Study of Disease in Children of the Royal Society of Medicine in November, 1922.

Medical Societies.

BRITISH CONGRESS OF OBSTETRICS AND GYNÆCOLOGY.

THE Fourth British Congress of Obstetrics and Gynæcology was held at the Royal College of Surgeons, Edinburgh, on April 19th and 20th, under the joint chairmanship of Dr. LAMOND LACKIE and Dr. HERBERT SPENCER. The societies taking part in the Congress consisted of the Royal Society of Medicine (Obstetrical and Gynæcological Section), Edinburgh Obstetrical Society, Glasgow Obstetrical and Gynæcological Society, Midland Obstetrical and Gynæcological Society, Royal Academy of Medicine in Ireland (Obstetric Section), Ulster Medical Society, and the North of England Obstetrical and Gynæcological Society. Dr. Lamond Lackie, as President of the Edinburgh Society, in a few words welcomed the members of the Congress to the ancient City of Edinburgh.

On April 19th a discussion was held on

INTRINSIC DYSMENORRHEA.

Prof. BLAIR BELL (Liverpool), in opening the discussion, said that originally the executive committee had hoped to introduce the discussion by issuing a joint report upon various aspects of the problem based upon information received from numerous centres. For various reasons this information had not been forthcoming and he had been asked at a few weeks' notice to prepare the opening paper. His remarks, therefore, were based upon the results of his own experience and results, derived from hospital and private patients, and from the statistical reports published by Marie Tobler, May P. Jacobi, A. E. Giles, and Catherine Chisholm. He had been surprised to find how little statistical evidence was available apart from that contained in the writings of the above authors. Statistics were of little value for the purpose of this discussion unless they were based upon healthy subjects. His own cases numbered 1000, of which 400 were private patients and 600 hospital patients.

Dysmenorrhœa was a condition which throughout the ages had been the cause of much trouble and speculation. It was mentioned even in writings 3000 years B.C. and later by Hippocrates. It was only within the last 100 years, however, that any attempt had been made to classify the various forms of menstrual pain into such types as "neuralgic," "congestive," &c. Marion Sims, in 1880, had first insisted that dysmenorrhœa was a symptom and not a disease, a point of view which no one disputes to-day.

The Classification of Types of Menstrual Pain.

The speaker considered, however, that the classification of the types of menstrual pain in common use to-day was not satisfactory, and in accordance with modern views based upon pathology rather than symptoms. He had suggested the terms "intrinsic"

and "extrinsic" as being more in accord with scientific fact. The word "intrinsic" meant "inherent," and included all forms of dysmenorrhœa due to some disturbance in structure or function of the local organs of menstruation or to general causes inherent in the individual. "Extrinsic" dysmenorrhœa meant pain due to some acquired lesion. The classification of intrinsic dysmenorrhœa which he used and taught was as follows:—

1. *Structural Anomalies*.—(a) Undevelopment of uterus: (1) Undevelopment with normal shape; (2) "cochleate" uterus with or without undeveloped ovaries; (3) acute flexions of fully developed uterus. (b) Gross malformations: (1) Congenital hypertrophy of cervix; (2) imperfect fusion of Müllerian ducts; (3) atresia of vaginal cervix with single or divided cavity.

2. *Physiological Anomalies*.—(1) Intra-uterine clotting; (2) exfoliation of the endometrium.

A Review of the Facts Elicited.

Prof. Blair Bell next proceeded to review in a series of 16 tables the facts derived from the investigation of his own cases and those of the authors mentioned. Table 1 showed the relation of the onset of intrinsic dysmenorrhœa to the age of the patient at the time of consultation. He found that in 400 private patients the average age of onset of menstruation was 15. The onset of intrinsic dysmenorrhœa was primary in 46 per cent. of cases, and secondary in 5 per cent., whilst the average age of the patients at the time of consultation was 33. In the case of 600 hospital patients primary intrinsic dysmenorrhœa was noted in 43.5 per cent. of cases, secondary dysmenorrhœa in 6 per cent., whilst the average age at time of consultation was 35½. Table 2 indicated the frequency of the different periods of pain in dysmenorrhœa. In 204 private patients the symptom was pre-menstrual in 26.5 per cent., intra-menstrual in 53 per cent., and post-menstrual in 1.5 per cent. In 18.5 per cent. it was both pre-menstrual and intra-menstrual. Intra-menstrual and post-menstrual pain was only present in 1 per cent. of 299 hospital patients. Prof. Blair Bell had found that out of 600 histories of hospital patients 63 per cent. complained at some time or other of menstrual pain. In 50 per cent. the dysmenorrhœa was intrinsic and in 13.5 per cent. it was extrinsic. In the case of girls, in a series of 600 hospital cases 43.5 per cent. of cases suffered from intrinsic dysmenorrhœa. In the case of 600 adults the incidence of intrinsic pain was 35 per cent.; 29 per cent. of this figure was continued from girlhood. With regard to the frequency of dysmenorrhœa in general in girls, Jacobi had found pain present in 53 per cent. of cases. Giles gave 65 per cent., Chisholm 42 per cent. Prof. Blair Bell's own figures were 46 per cent. in the case of private patients and 43.5 per cent. in hospital cases. As to the standard between primary and secondary dysmenorrhœa, the speaker had taken two years after the onset of the menstrual function. If pain began coincidently with menstruation it was "primary," if not until two years had elapsed he called it "secondary." Dysmenorrhœa was primary in from 67–69 per cent. of all cases of the intrinsic

type, and secondary in 7.5-9.5 per cent. Extrinsic dysmenorrhœa, on the other hand, was never "primary" on the cases investigated, but "secondary" in 21.5-25.5 per cent. In general the pain is primary in 67-69 per cent. and secondary in 31-33 per cent. of all cases in the experience of the writer of the paper. With regard to the influence of child-bearing on primary intrinsic dysmenorrhœa, Prof. Blair Bell found that out of 262 hospital cases, 68.5 per cent. had had children and of these 21.5 per cent. had been cured by pregnancy. In the case of 184 private patients, 53 per cent. had been fertile and 49 per cent. were subsequently cured. These figures were in striking contrast to those of "secondary" intrinsic dysmenorrhœa, for out of 57 cases all were sterile.

Treatment.

As regards treatment, if the uterus is undeveloped, Prof. Blair Bell advocated the administration of thyroid and ovarian extracts. This cures in a large proportion of cases. A uterus may be undeveloped even when the cavity appears to be normal in length as measured by the sound. Consequently the condition is easily overlooked. If the uterine cavity is shortened amenorrhœa is usually present. In the "pubescent" uterus, a common cause of intrinsic dysmenorrhœa, the cervix takes up half the length of the uterus, and a diagnosis can only be made under general anæsthesia. In the "cochleate" type, or "C-shaped" uterus, another common cause of intrinsic dysmenorrhœa, sections show an undue proportion of fibrous tissue. If such a uterus becomes pregnant, pregnancy leads to the replacement of the fibrous tissue by muscle and the menstrual pain is removed. Scanty menstruation means deficient ovarian substance. On the other hand, the ovaries may be fully developed even if the uterus is pubescent. Menorrhagia may then occur. The speaker did not think that the so-called "pin-hole" os uteri was a cause of menstrual pain. He had seen many cases without any dysmenorrhœa at all. If pain was present he attributed it to other developmental causes. With regard to the "cochleate" uterus, he had been much struck by its frequency and by the severity of the pain it produced. He had treated 51 cases by his method of anterior hysterotomy, and with excellent results. Many of these cases had previously been dilated and curetted without relief to their pain. The operation was not easy owing to lack of space, but the technique could be acquired with practice, and the results fully justified its adoption. It had been stated that congenital displacements of the uterus accounted for 45 per cent. of cases of menstrual pain. This was contrary to his own experience. The speaker had, however, noted the most acute pain in cases of congenital undeveloped uterine cornua.

With regard to the question of intra-uterine clotting, he was on debatable ground. Fibrin ferment was normally absent from the menstrual discharge, and he believed that it was extracted by the endometrium. Beckwith Whitehouse, on the other hand, had asserted that intra-uterine clotting was normal, and that it is broken up by thrombo-lysin secreted by the cervical glands. He personally did not believe that this was so, as the menstrual fluid is still of the same character after amputation of the cervix. He regarded all intra-uterine clotting as pathological, and due to the fact that the blood passes through the endometrium so quickly that the ferment cannot be extracted. He therefore used calcium lactate to tone up the uterus in such cases. As regards exfoliation of the endometrium, he had never seen the so-called "mucous casts." All casts not "endometrial" are formed of fibrin, and he thought that Cuthbert Lockyer's description of the case was not correct, as they were based upon material showing autolytic changes. True "casts" exhibit pre-menstrual decidual reaction in different degrees, and a typical "ground-glass" appearance due to intercellular exudate. All his cases were accompanied by menorrhagia.

Conclusions.

Prof. Blair Bell's conclusions were as follows: (1) Menstrual pain is relative. (2) The importance of pathology in the treatment and classification of dysmenorrhœa is one of the constant needs of to-day. (3) Intrinsic dysmenorrhœa is chiefly primary and is common; extrinsic dysmenorrhœa is secondary and very rare. (4) Under-development of the uterus is an important factor in intrinsic dysmenorrhœa as a cause. (5) Intra-uterine clotting is very common as a cause of extrinsic dysmenorrhœa. (6) Exfoliation of the endometrium is due to stripping up of the membrane by effusion of blood. (7) Empirical dilatation of the uterus is not only disappointing, but is keeping back the scientific study of this condition.

Dr. R. W. JOHNSTONE (Edinburgh) contributed a short paper on the

Results of Dilatation of the Cervix With or Without Curettage

from figures supplied by his own colleagues, Dr. Leith Murray and Dr. J. E. Gemmell, of Liverpool, and Dr. J. A. Kynoch, of Dundee; 576 cases had been investigated. 49.8 per cent. were permanently cured; 32.8 per cent. were temporarily cured or relieved; 17.4 per cent. were not relieved, and of these 4 per cent. were worse after the operation. Of 218 married women complaining of both sterility and intrinsic dysmenorrhœa, treated by dilatation of the cervix and curettage, 35 per cent. conceived and obtained complete or partial relief from dysmenorrhœa; 14 per cent. conceived without having obtained any relief. Two years had been taken as the period after operation, at which the results were judged. Graduated dilators of the Hawkins-Ambler type were used by Leith Murray, and dilatation being carried to $\frac{3}{4}$ in. (26 Hawkins-Ambler dilator). Dr. Kynoch and Dr. Johnstone had used dilatation by laminaria tents, but the speaker could not claim any better results, although theoretically the longer dilatation should be preferable. Stem pessaries were also used by Dr. Lamond Lackie and himself with good results. Pozzi and Dudley's operations apparently found favour with very few surgeons on the results received.

A Further Series of Observations.

Dr. GEMMELL (Liverpool) summarised a series of observations based on 350 hospital cases from 1904 to 1922. After-histories had been obtainable in 150 instances. Excluding all extrinsic causes, he considered that intrinsic dysmenorrhœa was due to faulty uterine contraction, as the result of a functional derangement. He grouped his cases as follows: Under-development of uterus, 34; mal-development of uterus, 210; acute ante-flexion, 160; acute retro-flexion, 6; atresia of cervix, 6. Investigation of this subject was difficult as, except in isolated examples, a complete pelvic examination was impossible. Further examination of the secretions during the periods was also difficult and distasteful to patients. No solid microscopic proof, apart from a few sections, was available to show actual structural alterations in the uterine wall, and he doubted the views set forward as to organic obstruction by membranes or clots as being a cause of pain. Clots in the vagina were no proof of clots being present in utero. They were absent in 47 cases and usual in 33 per cent. of patients. He thought that interference with the "polarity" of the uterus was common in mal-developments and probably accounted for the pain. Marriage appeared to increase menstrual pain rather than to diminish it, and sterility was a very usual accompaniment. His treatment was to dilate the cervix and curette, and introduce a gauze pack for 48 hours. The dilators he used were those introduced by Briggs and Grimsdale, often called the "Hawkins-Ambler" type. Of 68 cases, 44 per cent. had been permanently cured and 10 per cent. relieved for periods varying from three months up to several years. The failures amounted to 15 per cent.

Dr. HERBERT SPENCER congratulated Prof. Blair Bell upon his excellent paper. He was surprised,

however, to hear no reference made to the work of Hermann, Andrews, and Champneys. Also Prof. Blair Bell had made no reference to "intermenstrual" pain, the "Mittel-schmerz" of German authors. Dr. Spencer was in agreement as to the rarity of primary extrinsic dysmenorrhœa. Some years ago he had met with one case which he had since recognised was due to a utero-rectal adenomyoma. The worst case of menstrual pain that he personally had seen occurred in a Russian patient with a double uterus and vagina. Prof. Blair Bell had stated that only 50 per cent. of patients are cured by pregnancy. He wished to know what standard of cure was taken, as he thought that many more must be relieved at least. Personally he could recall very few cases of *absolute* cure in intrinsic dysmenorrhœa. Pozzi's operation did not seem to be much used in this country, but personally he had seen extremely good results. With regard to the operation of anterior hysterotomy, he regarded it as rather a severe operation in a young virgin. The old hysterotomy should do the same thing and much more easily. The operation described by Prof. Blair Bell did not appeal to him, and he thought it unnecessary. Further, he emphasised the fact that it was impossible to dilate a small cervix to 1 cm. without producing laceration. He had used laminaria tents many times, and his views coincided with those of Dr. Johnstone. He had also found stem pessaries useful, but was rather afraid of leaving the instrument in situ for any length of time.

Mr. CHRISTOPHER MARTIN (Birmingham) was of opinion that the subject was far too long for discussion, as in a way it covered the whole field of gynæcology. He thought that figures relating to dysmenorrhœa, whether obtained from hospital or private patients, were largely fallacious, as the majority of patients complain of menstrual pain. He was of opinion that much dysmenorrhœa might be prevented if girls were brought up on a more rational basis. Further, he thought that corsets should be avoided as they were a fertile cause of pre-menstrual congestion. Girls should have more exercise, and be brought up more as boys. Mr. Martin also referred to mild chronic appendicitis in childhood as being a factor in the causation of dysmenorrhœa in adult life. Dilatation and curettage per se he did not consider a satisfactory operation, but he had obtained good results by combining it with division of the posterior lip of the cervix. He thought that Prof. Blair Bell's operation was very difficult to perform in virgins with safety. In conclusion, he emphasised the danger of instituting treatment with such drugs as alcohol and morphia.

A Criticism of Terminology.

Prof. ARCHIBALD DONALD (Manchester) did not like the term "intrinsic" introduced by Prof. Blair Bell. The word means "inherent," and therefore a pain could not be called "intrinsic." Further, where is a line to be drawn, as the causation of menstrual pain is so diverse. He thought that the one class of case everybody could discuss was that of the young and apparently normal girl, engaged in some daily occupation—e.g., teaching, nursing, &c.—who every month, perhaps for one or two hours, is absolutely unable to "carry on" on account of the severe menstrual pain. This class of case was relatively *not* very common. In the majority of such he had found a "cochleate" uterus present. He did not agree that the cervix was always elongated and the corpus uteri small. Often the reverse was the case. Possibly, in addition, a defect in the endometrium exists which is so far unrecognised. He certainly had found a "diffuse adenoma" present in some cases. Further, he was not so pessimistic about the results of dilatation and curettage. In his experience 82 per cent. of patients were "improved." It was difficult to say how many were "cured." His practice was dilate to "19"—"20" dilator (Manchester pattern) and to scrape with a flushing curette. The uterus is packed for 24 hours. In former days he used to introduce a stem pessary, but never felt happy about leaving a foreign body in utero. One patient had

ceased to menstruate entirely as a result possibly from atrophy of the endometrium.

Divergent Views.

Mr. BECKWITH WHITEHOUSE (Birmingham) did not agree with Prof. Blair Bell's classification of the physiological anomalies of the uterus as a cause of intrinsic dysmenorrhœa, especially in relation to this question of intra-uterine clotting. Fifty per cent. of all women habitually and *normally* pass small clots from the uterus into the vagina during the menstrual function. He had stated this on previous occasions, and he repeated it again now. Also he did not believe that 50 per cent. of women suffered from intrinsic dysmenorrhœa, and he thought that the influence of the passage of clots on menstrual pain was very little. Prof. Blair Bell and he held divergent views upon the factors involved in the menstrual function, and he did not think that the arguments as set forward in any way refuted his theory. He had never stated that the secretion of the cervical glands contained thrombolytin. Also clots were almost always present in utero if a search was made. In health they were certainly small and easily overlooked, but he was quite convinced as to the correctness of his views. Further, the composition of the menstrual discharge in the human species can be accounted for on a much simpler hypothesis than by attributing any special power to the endometrium, such as the extraction of fibrin ferment. This was too far-fetched, and not in accordance with the facts as observed in the human species or of those in the realm of comparative anatomy. With the other aspects of Prof. Blair Bell's paper he was in complete agreement, and he heartily congratulated him upon the very thorough and exhaustive investigation. Personally, he limited the term "intrinsic" dysmenorrhœa to those very acute cases of menstrual pain which *totally incapacitated* the individual whilst it lasted, just as Prof. Donald had described. Accordingly, in collecting his own statistics his assistant, Mr. Danby, had disregarded a large number of mild cases of so-called "dysmenorrhœa" and had only investigated the "acute" type mentioned; 39 patients of this type had been traced. Dilatation and curettage had been performed in 23 cases, with cure in 6, relief in 12, and failure in 5. In two cases the operation was repeated with permanent cure after the second dilatation. Pozzi's operation had been performed twice with only partial success. One patient had had four abortions *after* the operation! Of 14 married patients 5 only had become pregnant, and of these 4 constitute 4 of 6 patients who stated out of a total of 14 that marriage had cured them. The deciding factor, therefore, appears to be not so much marriage as pregnancy, and, further, a pregnancy that *proceeds to term*. Abortion does not lead to that development of the uterus so essential to promote cure. Mr. Whitehouse noted that a so-called "cast" can be extruded from the uterus quite painlessly, as was the case with a patient seen by him a few years ago, who from the age of puberty had passed a typical "menstrual clot" each month for several years without any other hæmorrhage and without discomfort. There was no menorrhagia in this case, and the speaker regarded it as a reversion to the more primitive type of menstruation in the lower mammals.

One interesting point that had resulted from Mr. Danby's investigation of the total cases of dysmenorrhœa attending the General Hospital, Birmingham, was that the number of patients applying for relief during the past five years was almost double that of the preceding five years. Was this a psychological factor and part of the aftermath of war, or the result of unemployment and because women now had more time on their hands to think of their bodily ills?

Dysmenorrhœa as a Symptom of Uterine Maldevelopment.

Prof. R. J. JOHNSTONE (Belfast) pointed out that dysmenorrhœa is a symptom, and only a symptom, of uterine maldevelopment; 70 per cent. of women

suffer more or less pain at the menstrual epoch, but he, too, only regarded menstrual pain as dysmenorrhœa when it actually disables the patient. He did not think that any gynæcologist could cure completely true intrinsic dysmenorrhœa, but they could certainly relieve it very considerably. He was very glad that Prof. Blair Bell had made a clean sweep of the old terminology of "congestive" and "spasmodic" dysmenorrhœa, but he was very surprised to hear that the curative effect of childbirth appeared from statistics to be so slight. Had Prof. Blair Bell aimed at including in this category only ideal "cures"? He was also very glad to find such conditions as "conical cervix," "pin-hole" os, and "retroversion" left out of the list of causes of menstrual pain. They, in his opinion, were simply concomitants. He was interested in the account of anterior hysterotomy, but wondered whether it would stand the test of ten years' experience. With regard to the operation of dilatation of the cervix, he was not in favour of dilating to such degrees as some speakers had advocated. This was not "dilatation"; it was "divulsion." Also he did not believe in leaving solid bodies like "stem pessaries" in the uterus. One point had not been raised, and that was what is to be done with the patient who has had drug treatment and these various operations and still complains of severe pain? Personally he had lately used radium to produce amenorrhœa in this type of case.

The Degree of Disablement.

Dr. WATTS EDEN (London) observed that Prof. Blair Bell had made a very valuable contribution to our knowledge of dysmenorrhœa. He was surprised to find how frequent from the statistics dysmenorrhœa appeared to be. He could not believe that 50 per cent. of all women suffered from dysmenorrhœa. If this was stated then we do not all mean the same thing. Relativity of pain is a very important factor in the case, and we must have some kind of standard. Nobody expects the menstrual process to be free from pain entirely, but this is not dysmenorrhœa. The degree of disablement either as regards work or recreation is the true test. He was of opinion that taking this as a basis the number of *real* cases of intrinsic dysmenorrhœa was very small. He had placed under observation various so-called cases of severe menstrual pain, and practically all were found not to exist. As a matter of fact, he could only remember one *real* case of dysmenorrhœa in 10 to 12 years. He did not think it very profitable to employ any fixed terminology with regard to dysmenorrhœa, but he thought the term "intrinsic" better than the old word "spasmodic." The latter limited the field and made us take too narrow a view of the problem, disregarding such other factors as the parts played by the ovaries and other endocrine glands. With regard to the so-called "cochleate uterus," he was surprised to hear Prof. Blair Bell's figures. Personally he regarded it as being a very rare anomaly, although the anteflexed, retroposed uterus was, of course, common. The *small* anteflexed and retroposed or cochleate uterus was certainly not common in his experience. In many cases one cannot find any one anatomical point to account for menstrual pain. Dr. Eden also was not in agreement with Prof. Blair Bell's remarks as to the amount of uterine hæmorrhage being a criterion of the degree of uterine development. He was rather of opinion that an alteration in the balance of the whole endocrine organs may be a more important factor. The speaker referred to the alteration in menstruation produced by Graves's disease and myxœdema.

With regard to treatment, he had been much impressed with the operation of anterior hysterotomy when first described, but further experience had led him to the conclusion that it had no special advantages. It was the most difficult operation he had ever performed, and the end-results had been no better than with simple dilatation. He was in entire agreement with Mr. Christopher Martin as to the need for training of girls, although he did not acquiesce in the

need for abolishing corsets! One of the most useful lines of social research would be an extensive coördinated inquiry into the habits, games, and work of the adolescent girl and the influence of the same on the menstrual function. Dr. Eden, in conclusion, referred to the relief of dysmenorrhœa by means of atropine sulphate. In his hands, when given in doses by mouth of 1/100 gr. t.d.s. two or three days before, or during the menstrual function, atropine relieves pain to a remarkable degree. He thought that it might be tried with advantage in the 50 per cent. of cases where all surgical treatment fails, and where no obvious anatomical anomaly exists.

A Problem of Function.

Dr. J. FAIRBAIRN (London) observed that when he first received the questionnaire he was not at all clear what the word "intrinsic" meant. Was it a defect in "structure" with which we were concerned or was the problem one of "function"? He proposed to discuss the matter from the point of view of "function" only. Almost every speaker, with the exception of Dr. Eden, had looked on the *local* effects only. We were discussing a purely physiological function, and Prof. Blair Bell had attempted to show that 50 to 60 per cent. of all women were abnormal in this respect. Various types of uterus, "cochleate," and so forth, were described, but he wished to observe that no uterus was made to pattern, and simple variations had not been taken into account. Honesty of purpose did not always imply accuracy of observation. The views of the individual are tinged by his wishes. Dr. Fairbairn wished to lay stress upon the psychological aspects of the problem as apart from the anatomical and physiological. Pain varies from time to time. Sometimes it increases with the responsibilities of life, and is often acquired under stress, mental or physical. Frequently dysmenorrhœa is associated with very general nervous symptoms such as migraine, headache, &c. Prof. Blair Bell had rightly laid stress on civilisation and its influence upon menstrual pain. Nature means reproduction to follow directly upon menstruation, but the exigencies of civilisation prevent this. Another point to emphasise, also, is the modern tendency to recognise menstruation as *necessarily* being associated with pain, the so-called "poorly time." Girls should be brought up as boys, as had been mentioned by previous speakers. If pain was not *expected* it frequently would not appear. What we require, as Dr. Eden had pointed out, was a series of relative statistics relating to women under different circumstances. Here in Scotland, for example, what was the influence of out-door occupations upon the menstrual function? Dr. Fairbairn referred to Dr. Head's Croonian lecture on the Relief of Pain, and he looked forward to the time when more would be done by mental training rather than by operating. Like other surgeons, his results of dilatation or "divulsion" of the cervix were not good. Success in this respect, however, depends upon the psychology of the "operator" and the "operatee." He could not believe that pregnancy had so little influence in the cure of dysmenorrhœa, as he had seen so many good results from this cause.

Dr. HAIG FERGUSON (Edinburgh) thought that the last speaker was probably correct in his estimation of the psychological factor in the cause of pain. Where cases are *not* relieved at all, however, some developmental defect was probably at the base. He was interested to hear the good effect attributed to atropine by Dr. Eden, as he himself had also successfully treated dysmenorrhœa for many years with hyoscine and belladonna. With regard to the influence of ovarian function on menstruation, he quoted an instance of three patients in one family, the grandmother, mother, and daughter, who all menstruated only two to three times a year and yet all had large families.

Differences in the Character of the Pain.

Dr. GIBBON FITZGIBBON (Dublin) called attention to the difference in the character of pain in extrinsic

as compared with intrinsic cases. In the former the discomfort began several days before. The true intrinsic dysmenorrhœa he regarded as being due to spasmodic contractions of the uterus endeavouring to dilate the cervical canal. His standard had always been based upon interference with the patient's ordinary vocation. He agreed that the psychological factor was important but, after all, there was a very small number of real cases compared with the figures contained in Prof. Blair Bell's statistics. If the general health is improved dysmenorrhœa also often disappears. This is possibly due to balancing in the endocrine system. The speaker also drew attention to the fact that menstruation usually commences at 14-15 years of age, whereas with our civilisation sexual life does not generally begin until 25-26. Of his own cases of true intrinsic dysmenorrhœa 60-70 per cent. were cured by dilatation of the cervix. Sterility was cured in about 50 per cent. of cases. He had given up Dudley's operation as it never divided the os internum. He always carried the degree of dilatation to actual splitting of the os internum. If not the pain generally recurs. The longer the condition has existed the more difficult is it apparently to effect a cure. As to the onset of symptoms, Dr. FitzGibbon's own experience was not in accord with that contained in Prof. Blair Bell's first table. Hyoscine is a useful drug in diagnosing the anti-spasmodic from the spasmodic type of case. The speaker raised the question as to whether this condition of undevelopment of the uterus can be prevented. Personally, he thought it could by compelling the adolescent girl to take sufficient mental and possibly physical rest. He was much averse to mental over-exertion during the growing period and deprecated the present-day tendency to "examination pressure." Calcium is certainly an excellent tonic to unstriated muscle and thyroid helps in promoting uterine and possibly ovarian development. After all, however, pregnancy and a full-term labour is the best cure of dysmenorrhœa. With regard to anterior hysterotomy, he thought that as good results could be obtained by other means. It was a very difficult operation to perform.

Prof. B. P. WATSON (Edinburgh) observed that the first difficulty was the want of a proper definition as to the exact index of pain. He was in cordial agreement with Dr. Eden and Dr. Fairbairn about the importance of general hygienic treatment before any form of operative treatment was attempted. Dysmenorrhœa was often a general condition and not local, as shown by the accompaniment of general vaso-motor disturbance. Acute severe dysmenorrhœa, he thought all would agree, must be muscular and due to irregular disordered contractions of the muscle in the body of the uterus, or to spasmodic contraction of the fibres at the os internum. If relaxation of the fibres does not occur a want of polarity must be present. The coincident contraction of fundal and cervical fibres may be a contributory factor to the associated sterility so often present in these cases. He was of opinion that when any of the operations described do any real good, they do so by putting out of action the internal sphincter of the uterus. This accounts for the variability of cures. He prefers not to be content with simple dilatation alone, but to keep the cervical canal patent for six to seven weeks with a glass stem pessary. Cases which do not respond to this treatment or to plugging the uterus with a gauze pack are due, in his opinion, to irregular contractions of the uterine wall from excess of fibrous tissue. This can be helped by developing the uterine musculature with thyroid and ovarian substance after operation. Prof. Watson has used atropine very successfully and he noted that it acts in the same way by controlling unstriated muscle.

Co-education a Means of Improving General Hygiene.

Dr. BETHEL SOLOMONS (Dublin) favoured co-education of girls with boys as a means of improving general hygiene. He did not agree with Prof. Blair Bell's classification of dysmenorrhœa, as he thought it only tended to complicate the subject. The terms "constitutional" and "local" he considered equally met the

problem. He was surprised to hear from some speakers that the operation of posterior division of the cervix is still done. Dilatation of the cervix will do all that is necessary if it is pushed to the point of overcoming resistance. Division of the cervix usually results in a profuse leucorrhœa and lasting sterility. He agreed with Dr. Johnstone that cases unrelieved by dilators can often be cured by tents introduced in a sterile manner. It has been said that it is unnecessary to replace a retroverted uterus in a patient suffering from dysmenorrhœa. He had, however, seen several cases where a uterine fixation had cured and a previous cervical dilatation had failed. Dr. Solomons suggested that when dilatation does cure dysmenorrhœa it does so by possibly relaxing the cervico-uterine ligaments described by Hastings Tweedy.

Conclusions.

Dr. LAMOND LACKIE, in summing up the discussion, referred to the enormous diversion of opinion between various speakers. Apparently we were disagreed about the frequency of dysmenorrhœa, its causes, and its classification, and its possibility of cure. Prof. Blair Bell and many others regard dysmenorrhœa as being essentially due to mal-development of the uterus. Other speakers had emphasised the psychological elements. With regard to cure, Dr. Herbert Spencer had expressed the opinion that he doubts whether a cure ever does occur. Personally he had no doubt upon this point, as Dr. Spencer would have found if he had sent out a questionnaire. Prof. Watson thought that endocrine therapy would become more important as time went on. Dr. Lackie had not fallen in love with Prof. Blair Bell's operation of hysterotomy, but he was sure that the Congress was much indebted to him and also to Dr. Johnstone for the excellent papers and reviews which had been submitted.—Prof. BLAIR BELL replied.

ROYAL SOCIETY OF MEDICINE.

SECTION OF ANÆSTHETICS.

A MEETING of this section was held on April 20th, Dr. A. L. FLEMMING presiding.

Dr. J. H. CHALDECOTT opened a discussion on

CORONERS' INQUESTS: CLASSIFICATION OF DEATHS UNDER ANÆSTHETICS AS VIOLENT OR UNNATURAL.

He said that the invitation to open this discussion had been prompted by a letter from him published in THE LANCET recently; for the title of his paper he was indebted to a critic in the lay press, who reproached him for being unacquainted with the section of the Coroners Act which says: "On report of death the coroner, if he has reason to suspect the death to be a violent or unnatural one, shall hold a public inquest," and the writer went on to say: "And death from chloroform poisoning, whether immediate or delayed, is obviously unnatural." Dr. Chaldecott said he would endeavour to show, first, that in view of the attitude of coroners towards other surgical deaths it was not obvious that all anæsthetic deaths are unnatural, and, secondly, that it would be to the public advantage if inquests were not held on all anæsthetic deaths as a matter of routine.

Whatever points of difference might arise in the discussion there were two upon which all would agree—that there was nothing in their work which anæsthetists had any wish to conceal, and that the present discussion was not prompted in the slightest degree by antagonism or resentment towards coroners, either individually or collectively. Its object was to invite expressions of opinion as to whether the present interpretation of the Coroners Act in reference to anæsthetic deaths is the best possible for the community at large; and if not, how it can be improved.

Deaths under Anæsthesia and Deaths from Surgical Complications.

Dr. Chaldecott proceeded to contrast the procedure after deaths under anæsthetics and after those from,

say, surgical shock. Deaths occurring from purely surgical complications, even after operations of expediency, were not made the subject of coroners' inquests; why should coroners not exercise the same discretion in anæsthetic deaths, when the anæsthetic had been given by a qualified medical man, for a legitimate and natural purpose, and with the consent of the patient? Dr. Chaldecott contended that the fact that it is not the practice of coroners to regard surgical fatalities as violent or unnatural, proved that they have the power, if they think proper, to treat anæsthetic deaths in the same way. As to the advantages which the present system conferred upon the public, he could think of one only—that when the relatives or friends were dissatisfied a public inquiry cleared things up. He agreed that this was useful, and held that it should be applied not only to anæsthetic deaths, but to all deaths occurring under medical treatment where relatives thought they had cause for complaint, or when from information received the coroner suspected negligence, carelessness, or irregularity of any kind. Dr. Chaldecott had the impression, however, that relatives were almost invariably satisfied that everything possible had been done, and that a public and formal inquest was usually as distasteful to them as to medical men.

Disadvantages of the Present System.

Of the disadvantages, the most obvious was the terror of anæsthetics which the newspaper reports of these inquests created in the public mind. They were read by thousands of people who did not realise the enormous number of administrations taking place daily, and consequently failed to recognise that the percentage of fatalities is infinitesimal. This apprehension was detrimental in two ways: it greatly increased the patient's nervous and mental strain immediately before operation, and lowered resistance to shock; and, what was even more important, it frequently caused necessary operations to be postponed until the prospects of cure had been seriously impaired. Another ill-effect which reacted upon the patient was the additional strain which these inquests, and the publicity which follows in their train, impose upon the nerve of medical men. This was not entirely negligible even in senior men, but in those men who were on the threshold of their career the effect was much more keenly felt. Dr. Chaldecott instanced the case of a patient admitted in the night to hospital, desperately ill with advanced intestinal obstruction. The anæsthetist on emergency duty (probably a comparatively young man) was called upon to administer an anæsthetic for an operation which was at best a forlorn hope. It was quite possible that several such cases might occur within a few days. Suppose the first case died on the table, was it likely to steady the young anæsthetist's nerves when a crisis arose in his next serious case, if it flashed across his mind that for the second time in a week he might have to attend before the coroner to justify his administration? Could it be to the patient's advantage that the anæsthetist should have to bear this additional and unnecessary strain? There could be only one answer to that question, and this argument would apply with redoubled force if the surgeon were also called upon to attend the inquest. In a case of this kind the glaring anomaly was that if the surgeon and anæsthetist had allowed the patient to die without attempting to save him by operation, the death would have been regarded as natural, whereas because in spite of a strenuous effort he had died on the table, his death would have been suspected as being violent and unnatural, and a public inquest held. Dr. Chaldecott had once seen a pulmonary embolism occur in the middle of an operation, which was nevertheless completed; the patient was put back to bed, recovered consciousness, and died three hours later. The cause of death was certified as (1) strangulated umbilical hernia (three days); (2) operation; (3) pulmonary embolism (three hours). The certificate was accepted as one of natural death and no inquest was held.

Had the patient not recovered consciousness death would in all probability have been attributed to the anæsthetic. The operation killed the patient, so death was *natural*; had the anæsthetic—which was an essential part of the operation—killed the patient, her death would have been *unnatural*, and a public inquiry would have been held. It might be argued that these were extreme cases, and that a death during an operation of expediency, in which a fatality had been absolutely unexpected, was in a different category. Dr. Chaldecott thought that unless there was *prima facie* evidence of negligence or carelessness there was no reason to suspect this kind of death of being either violent or unnatural. It was difficult to understand why such death should be regarded as more unnatural than any kind of sudden death which occurred while the patient was under medical or surgical treatment.

In view of the fact that one branch only of medicine and surgery was singled out in this way for suspicion, it was not surprising that the administration of anæsthetics was the least popular of a doctor's duties. In hospitals the dread of possible trouble certainly had the effect of making house officers very shy of this work, and discouraged them from availing themselves of all the opportunities for anæsthetic experience which their office should afford them. This result was, of course, an additional disadvantage to the public.

Illustrative Cases.

Dr. Chaldecott quoted two anæsthetic deaths which occurred recently as illustrations of the harm inquests could do on the one hand, and of their uses on the other. The first was that of an aged man who died after he had been under the anæsthetic for some time. The autopsy disclosed fatty degeneration of the heart, which made it obvious that he might have died suddenly at any time; in this class of case an autopsy without a public inquest would have been quite sufficient, and would have done no harm, whereas a result of the inquest was a sensational report in the evening press, with the alarmist heading of "OPERATION RISK: HEART DISEASE THAT ESCAPES DIAGNOSIS." It would be difficult to imagine anything more mischievous and misleading. The impression which this would convey to many people was that a hitherto unrecognised danger had been discovered, instead of a common condition frequently the cause of sudden death, but one from which the patient may suffer without giving the administrator the slightest anxiety. The second case was one in which the patient lost her life through the transposition of the afferent and efferent tubes of a Junker's chloroform apparatus. This was an example of an accidental death in which an inquest was clearly called for, in order to ascertain whether or not the mistake was due to any negligence or carelessness.

Deaths Attributed to Delayed Poisoning by Anæsthetics.

These objections could be applied with even greater force to the holding of public inquests upon deaths which occurred several days after operation, such deaths being attributed to the indirect or delayed effect of the anæsthetic. In holding inquests upon this class of case the greatest inconsistency was shown. A large number of fatal complications might follow operations. What good purpose was served by an inquest on a case of delayed chloroform poisoning, which would not be equally well served by one on a death from shock, from secondary hæmorrhage, from pulmonary embolism, or for the matter of that, from ether bronchitis? In all these instances death would have occurred from complications which, taken together, represent an all-round percentage of mortality which is exceedingly low. Why should one complication be picked out and suspected of being violent or unnatural? It was common knowledge that the mortality of surgical operations was growing less and less. Would progress in surgical work have been so steady and continuous if every surgical death had been made the subject of public inquiry, and the surgeon had been called upon to explain and to justify his technique to a lay tribunal?

Surely the effect of such a custom would have tended to cramp surgical progress at every step. If the comparative safety of two methods of a particular operation, instead of being settled as they were now by surgeons comparing each other's results, were thrashed out in a coroner's court, would such a farce be in the public interest? Dr. Chaldecott argued that the selection of the anæsthetic in any particular case was a fair analogy. An inquiry addressed to anæsthetists as to the most suitable anæsthetic and method of administration for a particular case would produce various answers, all of which would be good; all would, at any rate, represent the studied judgment of an expert. At a coroner's inquest a complicated matter of this sort had to be settled as right or wrong by a single question and answer.

The Choice of an Anæsthetic.

For one who had never seen the patient during life to suggest to an anæsthetist in public, after a fatality, that he gave the wrong drug, was not only unjust but futile. The impressions conveyed to the lay mind by public discussions on the relative safety of chloroform and ether were almost invariably misleading, and Dr. Chaldecott suggested that such points were outside the functions of a coroner's court. These discussions, from a medical point of view, could do no good, and from a medico-legal point of view—the only point of view relevant at an inquest—could have no bearing upon the verdict. The growing popularity of ether in this country was in the opinion of most anæsthetists much to be commended, but anything resembling an official lay condemnation of chloroform and its consequent rejection in suitable cases would be calamitous. This critical attitude towards chloroform on the part of some coroners was already beginning to cramp the teaching of chloroform administration in the hospitals. An unqualified expression of opinion in court that ether is safe and chloroform dangerous must be quite inaccurate. It was known that in some cases, with some patients, and in the hands of some administrators, the position might be exactly the opposite. The outstanding fact remained that the best judge of the safest method on any particular occasion was the man who had to take the responsibility of the administration. In every one of these inquests the anæsthetist appeared to be on his trial, and was sometimes called upon to explain complicated technical points to a tribunal whose knowledge of the subject was negligible. This was a most unnecessary and unfair position to place him in.

An Alternative Proposal.

There could be only two reasons for holding these inquiries, firstly, to find out if anyone was to be blamed for the death, and secondly, to elicit some clinical fact which might be of assistance in diminishing anæsthetic mortality in the future. The first was really the prime function of a coroner's court, but in these cases it was unnecessary to exercise it unless there was ground for suspicion. For the second a coroner's court was the worst possible form of tribunal, and a substitute should be found. The medical profession would eagerly welcome any form of inquiry likely to be of practical use. Such inquiry should be official but private; it should be carried out by a committee, some members of which should be experts, who know enough of the subject to view the administration of anæsthetics from the point of view of the requirements of modern surgery. Such a committee should be appointed by the Ministry of Health, and should have the power to call for all records of the fatal cases—clinical, operative, and post mortem. In this way every point which might be useful in the future could be elicited and recorded without the danger of producing false alarms through indiscreet newspaper reports; and at the end of each year the committee could issue a report to the General Medical Council, which could be published in the medical press, containing any suggestions which they thought might prove valuable. If this procedure were adopted it would relieve coroners of holding inquests upon any of these fatalities, except those which present the special

features to which allusion had been made. The interests of the public would be better safeguarded, not only because the inquiries were being held by a tribunal competent to deal with the technical side of the question, but also by the absence of publicity. Dr. Chaldecott felt confident that the public would be quick to grasp the fact that their interests in this matter were inextricably interwoven with those of the profession; that anything which tends to cramp teaching, and to foster in the minds of young practitioners a fear of acquiring anæsthetic experience, must be a public danger rather than a safeguard; and that they would gladly support an effort to reform a system of inquiry which, however well adapted for murders, suicides, and ordinary accidents, was quite unsuitable for the majority of deaths in connexion with operations.

Immediate and Ultimate Mortality.

The PRESIDENT said that Dr. Chaldecott had taken as his main theme the safety of the public. There were probably many ways in which this could be better served than by the present system. The menace of a coroner's inquest was to the detriment of the public, especially as regards choice of anæsthetic. A young anæsthetist must be biased to some extent by the dread of publicity if things went wrong. Moreover, the anæsthetic that ensured that the patient would be got off the table in safety was not necessarily the best one for the patient. For example, in 100 cases of strangulated hernia in patients with bronchitis there would be a much higher ultimate mortality with ether than with other anæsthetics, though the immediate mortality might be lower. The patient was thus often deprived of the best method by this dread of a possible inquest.

Two Unusual Cases.

Dr. I. HAMILTON BEATTIE said that he had been asked to bring forward two unusual cases of interest in connexion with the subject under discussion. The first was that of a ruptured ectopic, practically moribund when admitted. Gas and oxygen were administered with Boyle's apparatus. On opening the peritoneum the patient was noticed to collapse. The usual restoratives were given, and heart massage was attempted, with no favourable effects. Adrenalin was then injected directly into the heart muscle. The patient rallied, and was taken to bed alive. She then developed Jacksonian epilepsy and died within two hours. The coroner did not call for an inquest. This was a matter of regret to the anæsthetist, as a thorough investigation of this case might have been of great scientific importance. The second case was that of a hopelessly incurable carcinoma of the lower jaw. The operation was undertaken with the object of making the patient more comfortable and of avoiding imminent rupture of the carotid artery. Colonic oil ether was the method of anæsthesia chosen. Three hours after leaving the theatre the patient died in bed without recovering consciousness. A post-mortem was ordered. The finding was that the primary cause of death was ether. This was, strictly speaking, correct, but was perhaps hardly fair to the anæsthetist, the circumstances of the case being considered.

Hospital Committee of Surgeon, Anæsthetist, and Pathologist.

Dr. Z. MENNELL pointed out that there are two classes of death to be considered: the first, due directly to the anæsthetic, the second due to the disease for which the operation is performed. The speaker had had to attend certain inquests recently in at least two of which the anæsthetist need hardly have been called upon to appear. In the first case the patient died under anæsthesia, a thoracic aneurysm having been ruptured by the surgeon's finger. In the second the surgeon, in operating on a cerebellar tumour, had incised the fourth ventricle. It was manifestly unfair to summon the anæsthetist to these inquests, unless the surgeon was called as well. At St. Thomas's Hospital there was a standing committee composed of a surgeon, a pathologist, and an anæsthetist, for the purpose of investigating deaths under anæsthesia. A form was

drawn up for the anæsthetist to fill and to forward to the committee, who discussed the case from all aspects. It was astonishing in how many cases deaths had nothing to do with the anæsthetic, being due to disease, to undue prolongation of the operation, or to some surgical catastrophe. In one or two cases deaths had undoubtedly been due to the anæsthetic. In these cases the inquiry proves unsatisfactory, because the corpse had been removed to the mortuary. Small portions of the organs were, however, sometimes obtainable, and it was extraordinary how valuable was the information then acquired. It was imperative that house surgeons, casualty officers, and resident anæsthetists must not be made even more nervous than they were at present. In answer to a question, Dr. Mennell said that the findings of the Medical Committee were sent to the Medical Committee of the hospital.

The Coroner's Point of View.

Dr. EDWIN SMITH, speaking as a London coroner who had also had experience as a general practitioner, said that a death from an anæsthetic was a death from a poison, and was not comparable with death from surgical shock. Inquests often had a happy result in appeasing relatives who had previously been dissatisfied. He considered Dr. Chaldecott's paper very logical and fair.

Dr. H. R. OSWALD agreed that of the vast number of cases anæsthetised the number of deaths formed an infinitesimal fraction, showing the care taken by anæsthetists. Coroners were by no means anxious to hold inquests on these cases, but were bound to do so on their interpretation of the law that such deaths are unnatural. The Coroners Act of 1887 clearly applied to these cases. On the whole, these inquiries were advantageous to the profession in general and to the anæsthetist in particular. People would be suspicious of an inquiry held in camera. He did not think it was necessarily an advantage that the case should be reported in the press; coroners had, however, no jurisdiction in this matter. To his own knowledge, in many cases friends of the patient had been convinced only after an inquest that the death was due to a cause not connected with the anæsthetic. In 1922, 925 inquests were held in his court, 25 being on deaths under anæsthesia. In not one of these cases was it found that the anæsthetist was to blame, but he might have been. It was true that coroners' juries were often composed of unskilled and half-educated people, and this fact added to their difficulties. He agreed that the anæsthetist and the surgeon, working together, were the best judges in the choice of anæsthetic. He objected to private inquiries because the vast common-sense of the majority of the people formed on the whole a very useful safeguard against injustice. Lastly, he emphasised again that according to the present state of the law coroners had no option, but were bound to demand inquests on these cases.

Certain Inconsistencies.

Dr. J. BLUMFIELD said that the coroners had not cleared away the inconsistencies in the nature of the cases in which they regarded death as unnatural. Was not death from the use of a knife as unnatural as death from the use of a poison? (At this point Dr. OSWALD intimated that a late coroner, Mr. Troutbeck, used to hold inquests on deaths after operation, and this had raised a great storm among surgeons.) Dr. Blumfield, continuing, said that the working of a knife and the infliction of a gas seemed to him comparable. Mr. Troutbeck's action had been unpopular with the profession on the ground that inquests were undesirable as a routine in deaths after operation, and Dr. Blumfield contended that they were also undesirable in deaths under anæsthesia. One point had emerged during the discussion—the complex nature of deaths of this kind. It was often a difficult matter to settle the cause of death, and the coroner's court was not the place where complex scientific problems of this kind could best be solved. The matter could not be adequately threshed out in these courts; and, moreover, according to the present

system, a lot of valuable material was lost. Post-mortem evidence was filed in one place, and clinical records in another. Both were incomplete, and it was difficult for an investigator to follow up the case from the beginning. In Dr. Blomfield's opinion Dr. Chaldecott had made out an unanswerable case for reform, but it was difficult to see exactly how it was to come.

Dr. M. I. FINUCANE asked what death certificate could be made out supposing inquests were not held?

The Medico-legal Aspect.

Sir BERNARD SPILSBURY said that the point of view of anæsthetists and coroners had been voiced, and he proposed to speak from that of a pathologist who had investigated many fatalities under anæsthetics. Anæsthetists seemed to have spoken under some misconception as to the law. A coroner was bound to hold an inquest on receipt of a notice of death occurring during anæsthesia, unless on inquiry he was satisfied that the death was a natural one. It was very difficult to be so satisfied without an inquest, and in London at any rate inquests were held on all anæsthetic cases. The object of an inquest was to find out whether a death was natural or unnatural, and if unnatural to ascertain the circumstances. In Sir Bernard Spilsbury's experience some deaths during anæsthesia were natural; such were the deaths from pulmonary embolism during operation. In these cases thrombosis had occurred, and at any time, before, during, or after an operation, the embolus might become detached, and sudden death ensue from pulmonary embolism. If the death were unnatural the conduct of the surgeon and his assistants, as well as the anæsthetist, came under review. The verdict might be that death had been "accelerated by the anæsthetic," or that death was the result of the surgical measures employed. Examples of the latter class were those of hæmorrhage from a blood-vessel or an aneurysm incised during operation and fatal cases of air embolism. In these cases the surgeon was held to be responsible. There was a class of case in which death could not be dissociated from anæsthesia. The influence of an anæsthetic might vary greatly. If the patient were moribund before the operation was started, the anæsthetic played a very minor part, and in some cases took no part at all. In such cases no great advantage was gained by an inquest. But there were also the deaths during anæsthesia of persons who were not seriously ill, persons in good general health, such as children who died suddenly during removal of tonsils and adenoids, or during the operation of circumcision. In these cases it was essential that a public inquiry should be held in the interests alike of the anæsthetist, the surgeon, the hospital, the relatives, and the general public. Few cases were more distressing to relatives who, after attending an inquest, were often satisfied that everything possible had been done, and that the cause of an unexpected death was cleared up in the coroner's court. If no public inquiry were held the patient's friends might well retain a feeling of suspicion or resentment. An indignant parent might then write to the press giving a perverted or exaggerated account of the circumstances. A special inquiry by a committee, such as was suggested by Dr. Chaldecott, would certainly be helpful from a scientific point of view, but would not replace the public inquiry in this class of case. In the speaker's opinion, the difficulty was not with the coroner's inquiry, but with the publicity which attended it. Inaccurate and misleading reports of inquests were published in certain newspapers, with comments intended to satisfy the craving for excitement of a certain class of reader. Such accounts of inquests in the press were certainly harmful. The coroner might perhaps authorise an accurate report of the case for publication. This was only a suggestion by which the difficulties and dangers at present attending the publication of coroners' inquiries might be met.

Dr. A. W. MATTHEW said that apparently Sir Bernard Spilsbury and certain other speakers were

anxious that coroners' courts should elucidate the cause of death. It was held by some authorities that the business of a coroner was only to see whether or not death was due to negligence. A coroner's court was not a pathological institute, and provided the coroner found no negligence, he was not officially interested in the cause of death. The coroner should thus be careful as to what questions he asked. A carelessly asked question might reflect on the anaesthetist.

Dr. H. P. CRAMPTON suggested a point of view that had not yet been brought out—the importance of the skill and speed of the operating surgeon with reference to the results of the anaesthetic; for example, a severe ruptured ectopic in the hands of an expert and rapid operator might do well, but if the surgeon were not so skilful, the patient and the anaesthetist being the same, a catastrophe might result. It was manifestly impossible for an anaesthetist to stick up for himself at an inquest to the discredit of the surgeon.

Mr. CECIL ROWNTREE said that in cases of spinal anaesthesia not only the anaesthetist, but the surgeon, the house surgeon, and theatre sister were summoned to the coroner's court, so that in these cases the position was even more complicated. If the dread of a possible inquest deterred inexperienced men from giving anaesthetics, it was a good thing.

Dr. H. E. G. BOYLE could not believe that coroners' juries had sufficient intelligence to give a verdict of any value in the question under discussion. They had to be guided entirely by the coroner. If inquiries were held by a scientific committee appointed and paid by the State, a mass of valuable detail would be collected.

Reply.

Dr. CHALDECOTT reiterated his opinion that inquests should certainly be held in all cases when relatives were dissatisfied. The other main point turned on the question, what was the law? If coroners were really bound by law to hold inquests on these cases and had no discretion in the matter, the law should be changed. He had thought that possibly this would not be essential; if a preliminary inquiry were feasible, and as the result of this the coroner was satisfied, the case could be referred to a scientific committee. If the coroner or relatives were dissatisfied, the inquest could be held and all records could then be forwarded to the committee.

GENERAL MEETING OF FELLOWS.

A GENERAL meeting of Fellows was held on April 23rd. Sir WILLIAM HALE-WHITE, the President, being in the chair, when a discussion on the

ETIOLOGY AND TREATMENT OF OSTEO-ARTHRITIS AND RHEUMATOID ARTHRITIS

was opened by Sir ARCHIBALD GARROD. He said that chronic articular disease was an obscure branch of medicine, the gross classification and multiple nomenclature of which were sure signs of ignorance. Osteo-arthritic lesions, erosion of cartilage, eburnation of bone, the formation of osteophytes, &c., developed insidiously in elderly people with a characteristic distribution, quite apart from infective rheumatoid troubles. Probably an underlying predisposing condition was excited by injury or wear or tear. Osteo-arthritic lesions might be produced by prolonged or recurrent inflammatory lesions, as in hæmophilia and in the rare disease of alcaptonuria, where ochronosis and other changes in cartilage were followed by a tendency to osteo-arthritic lesions in later life. As regards rheumatoid arthritis, a name to which he objected, as there was no connexion with true acute rheumatism and cardiac complications were absent, he inquired whether this was a definite disease or a mere residue left after whittling off cases of arthritis due to recognised causes. The clinical picture was definite in the distribution of the lesions, their persistence and the relapses which occurred, yet very similar pictures occurred in dysenteric and gonorrhoeal arthritis with differences only in the course of the disease. The arthritis of psoriasis was a definite form which was

much improved by treatment with arsenic in a case he instanced, only to relapse repeatedly and on each occasion in an aggravated form. The part played by septic foci—in the teeth or elsewhere—was still obscure; while such foci were undoubtedly the cause of many cases, no focus could be found in others even upon the most careful scrutiny. Evidence in favour of the separate entity of rheumatoid as opposed to osteo-arthritis lay in the peri-articular nature of the lesions, and the contracture deformities. Treatment had advanced very little. Infection foci should be attacked, and in this connexion he inquired how much good was to be expected from vaccine treatment alone. Drugs generally failed to achieve much; he considered guaiacol carbonate administered over a long period to be the most useful. Of protein shock he had little experience, and he wondered whether some of the dramatic cures obtained by it were lasting. Spa treatment was most useful when the acute stage was subsiding. The aim of treatment should be to kill off the infection before permanent damage had been done to the joints. In osteo-arthritis drugs were of very little use. Baths, electrical treatment, and adaptation of the habits to the disability, with treatment directed to the relief of pain, were all that could be done for the patient.

Rheumatoid Arthritis Not an Infection.

Dr. M. CASSIDY said that he considered that the importance of infective conditions in the ætiology of these diseases, particularly in the case of rheumatoid arthritis, had been much over-rated. He regarded the latter as a clinical entity, a somewhat uncommon disease, and one almost entirely confined to women. In his experience, it was uncommon to find a septic focus. Some years ago Dr. Cassidy and Mr. Percy Sargent had examined microscopically and bacteriologically small fragments of synovial membrane removed during life from rheumatoid joints. In only one of the 15 cases examined was an organism (a streptococcus) recovered. The speaker considered this positive result was due to a skin infection. He was sceptical as to whether rheumatoid arthritis was in any way infective. It might run a steadily progressive course for 30 or even 50 years with no complication other than fibrositis. Pleurisy, pericarditis, and endocarditis occurred rarely, and then probably accidentally. Rheumatoid arthritis tended to be hereditary; patients' relatives appeared to be specially liable to fibrositis. Dr. Cassidy's remarks referred only to genuine rheumatoid arthritis. Never, in his experience, was the relentless course of the disease arrested by extraction of teeth or a course of inoculation. There was, however, a large group of cases of chronic infective arthritis, which might resemble closely the former disease, in which infective focus was readily demonstrated, and when it was removed gratifying therapeutical results usually resulted. There were causes of osteo-arthritis other than infection. A joint which has been the site of repeated attacks of acute gout might eventually become osteo-arthritic. He had showed a year ago, at the Clinical Section, two sisters who exhibited numerous subcutaneous nodules above the course of the extensor tendons of the hands and feet. Some of these nodules, excised by Mr. Max Page, were found to contain abundance of uric acid. Both these sisters were now developing osteo-arthritic changes in the knees and other joints. And although neither case has suffered from an attack of acute gout, it was difficult to believe that this joint condition was not of gouty origin. The acute onset of osteo-arthritis of the knees, with or without Heberden's nodes in the fingers in women at the time of the climacteric, was familiar to all. Surely this condition must be metabolic rather than infective. He was fully alive to the dangers of chronic septic intoxications; perhaps the majority of all cases of chronic polyarthritides were infective, but he submitted there were other common, important, and easily recognised types, and he considered it retrograde to lump all these diseases together under the horrible title "non-

specific infective arthritis," as had been done in a recent (and in other respects admirable) text-book of medicine.

Distinction Between Osteo- and Rheumatoid Arthritis.

Dr. F. J. POYNTON said that it was over 20 years since he and Dr. A. Paine had demonstrated the experimental production of osteo-arthritis with a streptococcus, and rather later they showed experimentally that (1) the same infection in varying virulence might produce various types of arthritis, (2) that a monarticular arthritis might result from a blood infection. The various changes in the joints he looked upon as of great practical importance, but as secondary incidents connected with the prime cause and not in themselves specific. The problem of rheumatoid arthritis was unfortunately much more complex. It was in his opinion their lack of knowledge of the life-history of infection in the human tissues that was now an obstacle in the treatment of disease.

Treatment.—Dr. Poynton said that vaccines were indicated when a pure or almost pure culture could be obtained from an obvious local focus. Protein shock he abandoned before the war, but the recent paper of Perkins and Bruce required consideration. "Bowel infection" was the most popular theory at the moment; he regarded the colitis as an effect rather than cause of the disease in many cases, and was cautious in advising treatment by colonic douches. He had employed collosol iodine and sulphur, but preferred the syrup of the iodide of iron. Organotherapy was helpful in cases at the menopause and those with vaso-motor spasm. He curtailed carbohydrates, particularly for stout ladies with weak knees. Radiant heat he avoided in cases that had more pain in the summer. Ionisation had certainly seemed effective in cases of hypertrophic arthritis, though he was aware of the doubts expressed as to its efficacy. He was impressed with the frequency of injury as a factor in osteo-arthritis of the hip-joint. Treatment on the lines of tuberculous hip disease seemed the most reasonable plan in the early stages, but few patients would agree to this. In that case if they could afford it he thought the partial rest of spa treatment was useful in the early stage if the hip-joint was not worried.

Achlorhydria.

Dr. A. F. HURST dealt first with the importance of focal infection with special reference to secondary intestinal infection resulting from "achlorhydria." In those cases in which the disease continued to advance after all oral, pharyngeal, and nasal septic foci had been eradicated, the intestines had generally become secondarily infected, and the comparative frequency of achlorhydria in rheumatoid arthritis was noteworthy. Faber and Kahlmeister had found it present in about 36 per cent. of cases. It was present in about 4 per cent. of normal people. He had found it present three times in 14 consecutive private cases; definite hypochlorhydria present in four, and a low normal curve in three of the remaining 11 cases. Individuals with insufficient gastric secretion readily became infected, and this secondary infection required treatment by the administration of large doses of dilute hydrochloric acid, sour milk, and a vaccine prepared from any pathogenic organisms isolated from the duodenum by means of an Einhorn tube.

The Importance of Rest.—During the active stage of the disease tender joints should be rested and fixed in a good position to prevent deformity. Rest should be continued for weeks or months, and so save the patient from being ultimately crippled or bedridden.

The Psychological Factor.—The active disease died out sooner or later. When no pain or tenderness was present, rest was no longer required. Explanatory persuasion and re-education, with the aid of manipulation and massage, which were, however, of secondary importance, often resulted in remarkable cures. Only 18 months ago Dr. Hurst had shown, before the Clinical Section, a man, who had been completely bedridden, with his knees fixed in a flexed position

and unable to use his deformed hands for three and a half years, when he came under his (Dr. Hurst's) observation. As a result of the treatment mentioned there was no limitation of movement of his knees, which looked normal. He could walk miles, and, although his hands still showed the typical deformities, he could use them.

Dr. S. P. STRANGEWAYS exhibited pathological specimens from which he showed there were at least six types of arthritis at present included under the name rheumatoid arthritis. These he provisionally described as (1) capsular, (2) dry, (3) adhesive, (4) rarefying, (5) villous, (6) defective, and he gave detailed descriptions of the pathological appearances of each type.

Dr. J. A. GLOVER said that the Ministry of Health was making a statistical study of rheumatic diseases in which were included rheumatoid and osteo-arthritis. Regional medical officers and a number of insurance practitioners were collaborating in this work. The definition of rheumatoid arthritis adopted was "usually with an acute initial attack of pyrexia; many smaller joints affected; spindle-shaped joints; changes mostly periarticular, often symmetrical; nutrition usually bad; patients usually females. The definition of osteo-arthritis (including *malum coxae senilis*) was 'gradual onset, usually afebrile; fewer and larger joints affected; grating, lipping, eburnation, osteophytes; lesions often asymmetrical. Patient usually well nourished.'" A number of tables and diagrams were then shown from which the following emerged as salient facts. In males of all ages osteo-arthritis was nearly twice as frequent as rheumatoid arthritis, whereas in females the incidence of the two diseases was about equal. Rheumatoid arthritis was many times more common in females than in males. The incidence of both diseases showed a rapid rise amongst insured persons of both sexes in the higher age-groups (after 45 years of age). Thus, in the case of rheumatoid arthritis, the attack rate per 1000 in females rose from 7.60 in the age-group "45 to 54" to 49.13 in the age-group "over 65." The rise in the attack rate of osteo-arthritis in females was even more striking. In males a similar, but not so rapid, rise in the attack rate of osteo-arthritis was seen in the higher age-groups, but the rise in the case of rheumatoid arthritis was comparatively small. With these were shown also tables illustrating the fact that on the average patients with osteo- or rheumatoid arthritis had good teeth and a clean mouth in only 10 per cent. of cases, whereas 15 to 20 per cent. of controls suffering from other diseases passed this test.

Dr. W. J. MIDELTON was disappointed not to have heard continuous counter-irritation discussed in the treatment of these diseases. He had learned the value of this form of treatment from Latham and had now been practising it for 22 years with considerable success in chronic joint lesions. After multiple acupuncture a diluted croton oil was rubbed into the skin on several occasions. This often produced a severe dermatitis, but a striking improvement in chronic joint lesions was produced and in some cases complete cure. Photographs of cases so treated before and after the treatment were shown.

Dr. G. L. K. PRINGLE disliked the term "rheumatoid arthritis," which was apt to be used as a "scrap heap" for undiagnosed articular affections; further, patients regarded it as an incurable disease. He thought that four definite types were included under the heading: (1) Infective. (2) Chronic fibrous rheumatism in which the cartilages and bones were unaffected. This form sometimes followed gonorrhoeal rheumatism, but some cases might be of gastrointestinal origin. (3) An atrophic form often with nerve lesions, central or peripheral. (4) A villous form attacking the larger joints in middle life. For such patients it was advisable to cut down carbohydrates in order to reduce weight.

Dr. H. LYDIARD WILSON spoke of a form of bath employing moist heat which he had found useful in these cases.

Reviews and Notices of Books.

HELIO THERAPY.

By A. ROLLIER, M.D., Medical Director of the Institutions for Heliotherapy, Leysin. Oxford Medical Publications. London: Henry Frowde and Hodder and Stoughton. 1923. Pp. 288. 25s.

THE publication of Dr. Rollier's book in English comes at an opportune moment, as the widespread desire for further knowledge of the action of sunlight in health and disease has recently found expression in the appointment of a committee of investigation in this country. Those already acquainted with Dr. Rollier's writings will find that the volume now under review is not a mere translation of "*La Cure de Soleil*," but a new work containing much hitherto unpublished matter. The book is strengthened by the inclusion of chapters written by three of Dr. Rollier's assistants: Drs. Rosselet, Schmid, and Amstad, each of whom has special knowledge of some subject closely connected with heliotherapy.

Dr. A. Rosselet, who is physicist as well as physician, contributes a chapter on the Scientific Basis of Heliotherapy, in which he deals with a mass of heterogeneous and conflicting knowledge in the lucid manner of one who thoroughly understands his subject. A perusal of his article leads, nevertheless, to the conclusion that although the physical and meteorological study of light may be well advanced our knowledge of the mode of action of the sun-bath is still in its infancy. It is noteworthy that Dr. Rosselet now lays considerably less stress on the value of the ultra-violet portion of the spectrum than was the case in his earlier publications. Largely on account of the work of Sonne, this interesting group of radiations now appears to be eclipsed in importance by the luminous rays, which are not only able to penetrate the skin more easily than any other solar rays, but have also the curious property of raising the temperature of the subcutaneous tissues to a level several degrees higher than that of the skin, without any rise in the temperature of the body as a whole.

The greater part of the book is a record of Dr. Rollier's own clinical experience, dealing with the therapeutic action of the sun-bath, and the technique of heliotherapy as applied to the whole body and its several parts. This section is accompanied by notes of numerous cases, many of them illustrated by photographs, which afford convincing evidence of the value of modern conservative methods. Dr. Rollier is careful to point out the dangers of incautious exposure to sunlight, which may lead to serious and even fatal accidents. A focal reaction in a tuberculous lesion is liable to occur even when a distant part of the body alone is exposed to sunlight. This reaction somewhat resembles that caused by the injection of tuberculin, and is proportional to the duration of insolation and the amount of body surface exposed; hence the need for careful dosage, especially for those violently reacting cases showing peritoneal or pulmonary lesions.

The technique of the sun-bath in an average uncomplicated case would be as follows. After some days' initial rest in the fresh air sun-treatment is begun by uncovering the feet alone for three exposures of five minutes. The exposures are daily increased in duration and extent until on the fifth day the case will have, at ten-minute intervals, three sun-baths of 25-minutes' duration, uncovering first the feet and then, at five-minute intervals and in the following order, the legs, thighs, abdomen and thorax, the head being always shaded. By this time a fair idea is gained of the patient's tolerance, and if pigmentation be progressing well the exposures are safely lengthened, and reduced in number. The rate of progress of tolerance depends directly upon the rate of pigmentation, which is very variable, erythematous sunburn is never allowed to arise; non-pigmenting types with red hair and fair skin are from the first protected by thin gauze. Eventual success appears

largely to depend upon the successful management of the initial period of adaptation.

Cold, dry air is found to be a very important factor in successful sun-treatment, anything in the nature of a Turkish bath being dangerously relaxing; for this reason early morning exposures are advised in summer weather even in the high Alps, and of course are far more necessary in a humid climate such as that of our islands. Cases of lupus, for which the midday ultra-violet light is required, are given several short exposures toward noon in addition to the early morning bath. Dr. Rollier finds that by discontinuing the use of occlusive plasters in favour of light appliances involving a minimum of interference with the sun's rays, he has favoured the return of articular function and has avoided the muscular atrophy so commonly seen. A good development of the dorsal muscles is considered to be of great value in preventing the recurrence of spinal lesions. With this in mind the prone position is used for cases of spinal caries other than cervical and high dorsal; by this exposure of the back to the sun the dorsal muscles and skin are stimulated, atrophy and soreness are avoided, compensatory lordosis increased, and visible kyphosis diminished, but the adoption of this position is never advised until the focus of disease is both clinically and radiographically quiescent. Cold abscesses are not aspirated unless advancing in spite of treatment or threatening to open spontaneously, under which conditions only enough pus is withdrawn to relieve tension. Irritant injections have been given up, as reaspiration is thought to be more frequently necessary after their use. Contra-indications to sun-treatment are few, but they include hectic fever, renal insufficiency, and severe cardiovascular disease. Amyloid disease is, however, greatly benefited in a number of cases.

Routine operative treatment has been entirely abandoned, except for unilateral renal disease and for cases showing large inabsorbable sequestra, while in closed joint lesions practically the only excision that is ever advised is that of the knee-joint in rare adult cases where the disease is very torpid and ankylosis inevitable.

In a chapter devoted to the subject of Work Cure full stress is laid on the depressing and demoralising effects of inaction. Dr. Rollier encourages his bed-ridden patients to do light handicrafts, and his convalescents in more active pursuits. His views on the dangers of recurrence when a convalescent returns to the same bad conditions of life that produced the disease are one with those of British authorities, and, like them, he has found a partial solution of the difficulty in the working colony. He emphasises the value of a definitely anti-tuberculous environment for children who for various reasons are considered to be particularly liable to contract tuberculosis. The School in the Sun, near Leysin, is designed to provide such an environment for weakly children; health is here the primary consideration, and work and play alike are out of doors in open country, while clothes are reduced to sea-bathing proportions.

Dr. H. J. Schmid's article on the Radiographic Diagnosis of Osteo-articular Tuberculosis and Control of the Clinical Results of Heliotherapy contains reproductions of many excellent X ray positives. Dr. E. Amstad's chapter treats of the Radio- and Phototherapeutic Adjuvants of Heliotherapy. He has found no serious contra-indication to the simultaneous application of sun and X rays, provided that pigmentation be already present. He is of opinion that intense irradiation of active lesions always involves the danger of starting military tuberculosis, and is therefore unjustifiable. Discussing the treatment of tuberculous adenitis, he considers that it normally reacts but slowly to X radiation, and that those cases which show rapid regression after two or three exposures are of doubtful origin. Apart from adenitis he gains his best results with small superficial joints affected with the synovial type of tubercle; his third successful group includes the chronic fibrous adhesive type of peritonitis. Dr. Amstad's concluding chapter

deals with heliotherapeutic treatment in non-tuberculous diseases, such as rickets, general debility and anaemia, syphilis, open wounds, and lymphadenoma. Most cases of this last disease come under his care diagnosed as tuberculous adenitis, and in the majority a favourable, though temporary effect is observed, the general health improving and the disease appearing to be arrested.

Dr. Rollier's book is a magnificent object-lesson of what can be done by the intelligent coöperation of medicine and sunshine, and the principles which he has worked out have world-wide application.

HANDBOOK OF SANITARY LAW.

By B. BURNETT HAM, M.D., D.P.H. Ninth edition, by HENRY R. KENWOOD, C.M.G., M.B., F.R.S. Edin., D.P.H., Chadwick Professor of Hygiene and Public Health, &c. London: H. K. Lewis and Co., Ltd. 1923. Pp. xxviii.-244. 5s.

THIS useful little manual contains the concentrated essence of sanitary law for the use of medical students who are taking the diploma of public health. It should serve its purpose well. To post up in a publication of this kind the latest changes of the legal kaleidoscope must, however, be a heart-breaking task. Several pages, for example, are devoted to the Sale of Food Order, 1921, which has now only a limited operation. Part II. of the Order has now been replaced by the Sale of Tea Act, 1922; the bacon and ham provisions of Part III. are dead; so are Parts IV. and V., which dealt with jam and fats. These changes occurred early in September, 1922, but were apparently too recent for inclusion. Again, almost all the references in this handbook to statutes about education and the employment of children require correction since the operation (on Oct. 1st, 1922) of the big repealing and consolidating Act of 1921. No better illustration of the intricacy of our sanitary law, to which we refer in a leading article this week, could be furnished. The clamant need of applying the consolidating process to our public health legislation has frequently been emphasised of late. We observe that the preface to the original edition of this handbook pointed in the same direction 24 years ago.

TUBERCULOSIS.

The Cure of Tuberculosis and Its Mixed Infections by Cutaneous Inoculation. (Die Heilung der Tuberkulose und ihrer Mischinfektionen durch Kutanimpfung.) By Sanitätsrat Dr. Med. W. PONNDORF. Leipzig: F. C. W. Vogel. 1923. Pp. 189. 6s.

THE treatment advocated by the author is the inoculation of vaccines into scarifications on the outer aspect of the arm. He uses two vaccines. "A" is for pure tuberculosis, and "B," which consists of the constituents of "A" plus the endotoxins of streptococci, staphylococci, pneumococci, and influenza bacilli, is for tuberculous mixed infections. By "tuberculous mixed infections" the author means almost every infectious disease to which man is prone. Although he has given more than 50,000 inoculations in the course of more than ten years, he has not once seen sepsis supervene, and he has only thrice observed anaphylactic shock follow the inoculation of tuberculin. The foundation of his system is the hypothesis that the skin is capable of reacting to the local application of toxins with various immunising responses. To prove his case Dr. Ponndorf does not stoop to the use of statistics; he had not time to prepare a statistical analysis of all his cases. And to make good the deficiency—if it be a deficiency—he has filled his book with reports of a great number of illustrative cases. The most remarkable feature of this collection is its polymorphism. It contains all, or nearly all, the pure manifestations of tuberculosis. There follows an almost infinite variety of diseases all responding to the author's

treatment in a manner delightfully simple and uniform. Only when he discusses pulmonary tuberculosis in the last stage does his optimism seem to flag, and even here he has been able to prolong life and mitigate symptoms. The work of Prof. Sahli and others suggests that tuberculin given through the skin may have a definitely beneficial effect, and Dr. Ponndorf may be on the right track. But there is an atmosphere of the Arabian Nights in his book which is apt to dazzle the reader.

JOURNALS.

JOURNAL OF LARYNGOLOGY AND OTOTOLOGY. January and February, 1923.—The January number opens with a summary by Dr. Henry Hall Forbes, of New York, on the present status of radium in laryngeal and cesophageal cancer in the United States. The impression given is that a certain number of cases can be definitely improved, that in a few a disappearance of the growth has resulted, and that in the opinion of some observers pre-operative radiation is of great value. The method most in favour for the treatment of laryngeal cases is to bury needles or small capsules containing emanation. Useful technical details are given.—Sir William Milligan contributes an article on the diagnosis of septic sinus thrombosis. The temperature record is one of the most important and reliable of diagnostic signs; an almost continuous, or at least two-hourly, record should be kept. Frequent oscillations of from 1° to 3° are quite common in commencing thrombosis, whereas sudden oscillations of more than 1½° are unusual in uncomplicated mastoiditis. Rigors only occur in about half the cases, and their absence should by no means negative exploration. A feeling of chilliness, with cold hands and feet, is an important symptom. Slight engorgement of the retinal veins is a valuable sign, which can only be estimated by daily examination. A high degree of leucocytosis is suggestive of pus, but by no means necessarily of pus in the sinus. In very rare cases septic thrombosis may occur when there has been but a fleeting tympanic suppuration, and after the membrana tympani has already healed.—Major W. S. Patton gives an account of the identification of the diptera which cause naso-pharyngeal and aural myiasis in man, which should be of use to practitioners within the tropics.—Sir StClair Thomson provides a "critical review" on aperioidic spasmodic rhinitis, based on a Paris thesis by Dr. Georges Dhers on the treatment of this condition by hypodermic injection of the patient's own serum.

The February number opens with some further remarks by Dr. Irwin Moore on angiomas of the larynx, supplemental to a review of the subject which appeared in the *Journal of Laryngology* last year. He concludes that the intra-laryngeal removal of sessile angiomas is a dangerous procedure owing to the risk of secondary hæmorrhage.—Dr. T. Ritchie Rodger discusses the pathological effects of excessive sounds on the cochlear apparatus. From an examination of 48 boiler-makers in Leith he found that, in lads who alleged that they were not at all deaf, there was always some diminution of hearing for forks of 419 and 512 vibrations per second, corresponding to the pitch of the noises predominant in the shops. In men who had been at the work from 10 to 30 years there was some depreciation all along the scale, but more marked for the medium forks; while in very advanced cases the depreciation was uniform. He believes that these findings, together with the results of experiments on guinea-pigs exposed to continuous sounds, give support to Helmholtz's resonance theory of audition.—Mr. Francis Muecke reports two cases of temporo-sphenoidal abscess, with recovery; and Dr. F. G. Wrigley a case which died with symptoms of peritonitis on the third day after the abscess was opened.—Mr. Herbert Tilley describes two fatal cases of osteomyelitis of the frontal bone, both of which occurred after operation on the maxillary antrum, and in both of which the frontal and ethmoid sinuses were previously diseased.

THE LANCET.

LONDON: SATURDAY, APRIL 28, 1923.

THE NEED OF A NEW PUBLIC HEALTH CODE.

IN his Chadwick Lecture, which we printed in THE LANCET of April 14th, Dr. CHARLES PORTER commented on the number and complexity of the Acts which comprise the public health code of this country. It is now just three-quarters of a century since the first Act was passed "to promote the Public Health" of England. That piece of pioneer legislation was gradually entangled in a network of amendments and extensions as the national health conscience was quickened. The result was such confusion that at length, in 1875, the mass of overlapping enactments was reduced into one symmetrical Act consolidating all the provisions applicable to England and Wales with the exception of the metropolis. This was a notable step, but since that date we have been content to mark time. The law of public health is now to be found primarily in the half dozen measures collectively known as the Public Health Acts 1875 to 1907, and secondarily in some 30 others ranging from the Rivers Pollution Act of 1876 to the Venereal Disease Act of 1917. To this catalogue we must add not only the special health legislation for London, but also the wide range of local Acts which, as we have pointed out on previous occasions, gradually advance the standard of hygiene in every part of the country until the improvements which all localities are anxious to secure are ripe for incorporation in an Act of universal application. Nor ought we to ignore allied subjects such as housing, mental deficiency, maternity and infant life protection. Pausing at this point and looking no further, we are faced with an immense congeries of statutes, successively amending, repealing, applying, and extending one another, a chaos of piecemeal law-making which calls urgently for that same process of simplification and consolidation which last took place in 1875. Almost without exception these enactments were passed before our Ministry of Health was constituted in 1919 with its statutory duty to "take all such steps as may be desirable to secure the preparation, effective carrying out, and coördination of measures conducive to the health of the people."

When are these steps going to be taken? Year after year the Select Committee on Local Legislation urges the consolidation of the Public Health Acts. Members of Parliament have lately been pleading for a system of draftsmanship which will produce simple and comprehensive statements of our laws. A Consolidation Bill, as Lord HALDANE has observed, has the special value of focusing its subject and of making a new starting-point for reform and fresh legislation. The process of consolidation has frequently been applied with the happiest results. There is nothing particularly formidable about it. Three measures of this kind received attention last year, one of which (dealing with the law of salmon fisheries) is likely to be passed this session. The Parliamentary Counsel's Office usually has several Consolidation Bills on the stocks. Such Bills are, as a rule, referred to a Joint Select Committee of both Houses, which considers the question how far they state the existing law. If the Committee is satisfied, then Parliament

is usually satisfied too. The intricacy of its subject and the length of its clauses are no obstacle to the passage of a Bill through Parliament; otherwise Lord BIRKENHEAD's colossal Law of Property Act would not have been dealt with so comprehensively by a somewhat uncomprehending legislature. So technical a topic as the law of trusts in Scotland was condensed two years ago by a band of experts from a score of old Acts into one complete, orderly, and accessible whole as valuable to lawyers as it was convenient to Scottish citizens. It is true that public health law consolidation does offer something of a problem in the selection of the matters to be included. It might be hard to draw the line between Public Health Acts which deal with housing and Housing Acts which raise points of hygiene. But the difficulty is no greater than that successfully surmounted in the consolidating Education Act of 1921 which, in substituting one new Act for 25 old ones, elected to include central and local authorities, teachers and teaching, medical inspection, the duties of parents, and the employment of children, while excluding the law of industrial schools and educational charities. Parliament at any rate made no difficulty about passing either of these Acts; on the contrary, it welcomed them. Why, then, does the law of public health wait so long for simplification?

In asking this question earlier in the present year we mentioned certain stumbling-blocks. Parliamentary time is absorbed by partisan measures. Consolidation proposals do not dominate general elections. Administrators and text-book writers have a sentimental love of the technical complications wherein their apprenticeship was served. A more substantial difficulty is the fact that consolidation and amendment do not go easily together. There is little doubt that our public health law wants both of these, though we would sooner have consolidation minus amendment than no consolidation at all. A Bill which merely replaces existing law has always a good chance of being treated as non-controversial; but if the title of the Bill is not only "to consolidate" but "to consolidate and amend" the law, it is an invitation to every Member of Parliament to introduce matters of controversy which may wreck the prospects of success. GLADSTONE, we believe, made it his rule in such a case to introduce two parallel Bills, the one to contain the amendments, the other to comprise the consolidation. As soon as the former was passed it was possible to catch up the amending provisions and incorporate them in the latter. The plan is simple, and if we are all agreed that the time has come to evolve order out of the chaos of our health laws, a beginning can be made forthwith. It would take but very few weeks for the Minister of Health to determine, with the greatest possible measure of common agreement, what amendments are necessary and acceptable. A Bill to give effect to these could be prepared in a few days; indeed, most of its clauses already exist in local Acts. Meanwhile the Bill to consolidate and contain the whole law of public health should be put in hand. We have no reason to suppose that the Ministry is hostile to the course we are suggesting. It is even probable that the materials for a consolidating Bill already repose in some official pigeon-hole. In order to ensure that that repose should not endure for ever, it is desirable that all who are concerned in public health administration should press for early action. There are few objects which a Member of Parliament might with a greater disinterestedness be canvassed to support or which a public body might with better reason pass a resolution to recommend. If all concerned will ask for it,

the request will receive attention. If they remain inarticulate, other measures will naturally be preferred. Consolidations of National Health Insurance and of housing law possess, we understand, a better chance of early success. Such measures are wanted and will be welcome; but we should like some assurance that the older and certainly not less pressing claims of public health legislation will be met within the next twelve months. Not the least advantage of such a consolidation would be the opportunity it would create for a similar consolidation of the departmental regulations concerning public health. These are now as scattered and as inaccessible as the Acts themselves.

TISSUE CULTURE.

WE publish in our present issue the second and third of a series of three lectures by Dr. A. H. DREW on the cultivation of tissues in vitro, and a further paper by the same author containing additional technical details appears in the current number of the *British Journal of Experimental Pathology*. Originally used by ROSS HARRISON in the study of nerve cells, this technique was adopted by CARREL and his fellow-workers for the study of tissue growth in general, and has been employed extensively both in America and in this country for ten years or more. It was a line of research rich in promise, but it must be confessed that its fruits have hitherto been meagre and far from encouraging. Dr. DREW's lectures, however, describe observations of the first importance, which, it is safe to say, must have a profound influence on this branch of biological science. In this line of research technique is, indeed, everything, and much of Dr. DREW's success is due to the discovery of a saline mixture which, enriched with rat or mouse embryo extract, is capable of replacing the much less convenient plasma medium previously used. In this medium embryo and adult tissues are cultivated with comparative ease. If such cultures are exposed to ultra-violet light for ten minutes the cells are killed; but by protecting certain selected portions of the culture from the rays by a globule of mercury, isolated uninjured cells are preserved from which pure cultures can be obtained. In these cultures the cells grow as undifferentiated sheets of tissue. If now connective tissue is added to the culture, the epithelial cells undergo a characteristic differentiation. In kidney cultures tubules are formed, and in cultures of alveolar mammary tissue acini develop. Although adult tissues can be propagated with ease in the artificial medium, their growth is very slow compared with that of embryonic tissues. If, however, an extract of autolysed cells is added to the medium, adult tissues now grow at the same rate and with the same luxuriance as embryonic tissues. In other words, the phenomenon of wound repair is reproduced in vitro, and it is abundantly demonstrated that repair depends upon chemical excitation, and that theoretical considerations of the interdependence of cells, of variations of internal tissue tension, are unnecessary. Possibly the most significant observation of all is this—a simple non-autolysed extract of the cells of a malignant growth is capable of replacing the autolysed normal cell in this experiment. The malignant cell, in fact, contains already formed those growth-stimulating substances which are only liberated from the normal cell when it undergoes autolysis. With characteristic reticence, Dr. DREW gives no hint of the direction in which these investigations may be expected to lead. But it requires little imagination to appreciate their extreme importance not only in general pathology, but in the more limited field of cancer research.

THE TEACHING OF MIDWIFERY AND ITS DEFECTS.

WE summarise in another column the main points of Dr. JANET CAMPBELL's report to the Minister of Health on the existing arrangements for teaching obstetrics and gynaecology in the medical schools of Great Britain. This report appears most opportunely inasmuch as the authorities of the medical schools must shortly be considering the best methods of utilising the extra year which the General Medical Council have recommended should be added to the curriculum of the medical student. The Council have advised that at least three years should intervene between the date of passing the examination in anatomy and physiology and the final examination in medicine, surgery, and midwifery, and they have further recommended that the professional examination should include clinical and practical tests in midwifery and gynaecology, or that, failing these, the students must produce duly attested records of the clinical work done by them, to be taken into account, if necessary, by the examiners in assessing the results of the examination. It is clear from these recommendations that the Council wish to insist upon a higher standard of teaching than has hitherto obtained in these subjects, and that they intend that the status of the examination should at least be equal to that in medicine and surgery.

The training of the medical student in gynaecology is on the whole adequate; the subject is not an extensive one, and so far as it is possible—obviously not an easy matter to arrange—the student gets a fair amount of instruction in practising the methods of examination which constitute the main difficulty in mastering the practical application of this branch of medicine. In regard to midwifery the position is, however, far otherwise, and this report lays very bare indeed the great inadequacy of the clinical teaching of what is after all to many young practitioners the most important branch of their medical training. The causes for this are plain and have been set out before in our columns. They are mainly three in number: the inadequate number of beds devoted to this subject in the great majority of the teaching hospitals all over the country; the fact that in an extern department, which is often all that is available, proper teaching is almost impossible; and, thirdly—most important of all—the teaching in practical midwifery is mainly in the hands of junior men not of the standing nor with the experience of the teachers engaged in training the student in medicine and surgery. This is to a large extent unavoidable under present conditions. Practical midwifery teaching cannot be done at set hours or to large classes; it must be carried out when the opportunity offers and must be largely individual in character. Bedside teaching on labour cases by senior members of the staff can only be attained when such teachers are resident and always available, a condition of things which, apart from the Rotunda, does not obtain in any lying-in hospital in the British Isles. When we consider the relative importance of the two subjects of midwifery and gynaecology, the proportion of obstetrical beds in the large hospitals with medical schools attached is seen to be too small—quite insufficient for teaching purposes, even if, when provided, they were always available entirely for medical students. Only too often they have to be utilised also for the training of midwives. This state of affairs will not be remedied until the managing committees and the medical and surgical staffs of the hospitals are induced to give up an adequate

number of beds to other subjects by the examining bodies laying down definite regulations dealing with bedside teaching in midwifery, which must be observed if the hospitals desire to remain as medical schools.

Nothing that can be done in an extern department will be sufficient to teach the student properly unless it can be combined with proper training under skilled supervision in lying-in wards. It is very probable, indeed almost certain, that if such regulations were made, the necessary number of beds could be forthcoming at some sacrifice on the part of the other members of the staff in all the larger hospitals with medical schools attached. If the number of beds were adequate, then the provision of proper teaching by members of the senior staff would not be a difficult matter to ensure, as it could be made a condition on appointment. With the additional year which will soon be available for the clinical training of the medical student there should then be no difficulty in providing a sufficient period of training; and just as at the present time he has to spend six months clerking and dressing in the medical and surgical wards, so he could profitably be engaged for six months in the gynæcological, obstetric, and infant welfare departments, which should all be closely associated. Such a period would also afford time for proper training in an ante-natal and post-natal department, the ante-natal work being perhaps the most important of all. The present-day tendency to separate midwifery and gynæcology should be resisted, and the teacher of the former subject should remember, what in many instances he seems inclined to forget, that, as Dr. CAMPBELL points out, it is the skilful, non-operative management of ordinary labour which the general practitioner needs to understand; and this must remain the fundamental teaching of even the most skilled obstetric surgeon. When adequately trained in the lying-in ward and in a position to derive benefit from such work the student can learn a great deal more in the extern maternity district. He can here gain experience in the households of the poor which cannot fail to be of the greatest advantage to him in after years, and further, he can learn to practise the various ways of carrying out antiseptic methods in the patient's own home which will be of service to him in private practice. We look forward with Dr. CAMPBELL to a time not far distant when all practitioners will be thoroughly trained in obstetrics and will possess the knowledge and sympathy needed to bring about a partnership with local authorities and the State. Without such coöperation the most fruitful results of public and voluntary effort for the welfare of mothers and children cannot be obtained.

A HARMFUL PENSIONS BILL.

THE Bill which is being introduced in the House of Commons by Mr. F. O. ROBERTS, Member for West Bromwich, would, if enacted, alter completely the fundamental basis of entitlement and have far-reaching effects on the large body of medical men concerned with pension work. Its effect would be so to amend the War Pensions Acts that any disease or incapacity found in any officer or man at any date after he has left the Service is to be considered attributable to or aggravated by service unless the contrary is proved. The Bill further states that "for the purpose of this provision, acceptance for such service shall be conclusive that at the time of joining such service the officer or man was not suffering from any such disease or incapacity." This Bill is the

practical application of the "fit for service: fit for pension" deduction, and therefore merits all attention. Those who worked on the medical boards of the Ministry of National Service will remember the four grades into which the examinees were grouped: that Grade II. included men subject to partial disabilities, and that Grade III. was composed of men with marked physical disabilities or such evidence of past disease that they were not considered fit to undergo the degree of physical exertion required for Grades I. and II. Excluding the rejected Grade IV. men, 2½ million men were passed as fit for some form of service during the operations of the National Service Ministry—i.e., during the 12 months immediately preceding the signing of the Armistice. Of these 871,769 were placed in Grade I., 546,276 in Grade II., and 756,859 in Grade III. Excluding the rejected Grade IV. men, 25 per cent. of those who were accepted fell into Grade II. and no less than 34 per cent. into Grade III. The Committee who reported on the work of the Ministry of National Service saw no reason to believe that the 2½ million men examined were other than a fair sample of men of military age in this country, and it is fairly clear that when subjected to the test of actual historical fact the argument that acceptance for service is proof that the officer or man was not suffering from disease or incapacity crumbles and disappears. We are, however, not so much concerned with this aspect of the proposed alteration of the Warrants as with the consideration how the alteration would affect the medical men who would be required to carry it out. The medical attitude to the men examined has been invariably one of scrupulous fairness and sympathetic attention. Under the proposed conditions every ex-Service man who, being ill or incapacitated for whatever reason, however long after the war, claimed pension would be entitled, on the face of it, to a decision in his favour, whatever the medical view, unless the Ministry—*videlicet*, the medical men employed by the Ministry—were able to offer medical facts in disproof. It would indeed appear that the only occasion for medical assistance in the determination of entitlement to pension would be that of obtaining evidence in rebuttal of the claim. Whether medical men would consent to carry out this unenviable task, or, if they consented, would succeed in obtaining the necessary coöperation of those in attendance on ex-Service men to whose claims their evidence might prove adverse, must be open to doubt. It seems certain that the existing relations between the body of medical men engaged in pensions work and the pensioners would be profoundly altered—for the worse.

THE King and Queen will visit the new buildings for the Department of Anatomy and for the extension of the Institute of Physiology at University College, London, on May 31st, and will lay the foundation-stones of the new obstetric block and of the nurses' home connected with University College Hospital.

THE LATE DR. P. MULDOON: AN APPEAL.—A few weeks ago Dr. Patrick Muldoon, of Mohill, co. Leitrim, Ireland, was shot dead in the street near his own house. The circumstances of his death have never been cleared up. He was a young man of 31, married, with three children, the eldest only 4 years old. He had already won respect in his profession, both from his brethren and from the public, and a successful career seemed to be open before him. Naturally he had not been able to make adequate provision for his family. An appeal has been issued on their behalf, and subscriptions towards it will be received by the Very Rev. Canon M. Masterson, of Mohill, and by Drs. Chas. Dolan and Thos. Reynolds, of Ballinamore, co. Leitrim.

Annotations.

"Ne quid nimis."

ROYAL MEDICAL BENEVOLENT FUND.

THE urgent needs of benevolent funds to relieve distress within the medical profession will occupy the attention of the annual meeting of this Fund, to be held this year at the Royal College of Physicians, Trafalgar-square, London, on May 7th, at 4 P.M. Sir Thomas Barlow, the President, will be supported by Sir Humphry Rolleston, Sir Anthony Bowlby, and Sir William Hale-White, and addresses will be delivered by the Archbishop of Canterbury and Lord Sumner. The objects of the Fund—(1) to make grants of money to distressed members of the medical profession, their widows, or orphans; (2) to provide annuities for such after they have reached the age of 60 years—are well known to our readers, but the support given is still meagre. The number of new applicants for help in 1922 was nearly double that in previous years, and the value of the grants was also considerably larger; the total number relieved was 483. The income from subscriptions during the year amounted to £3503 and the grant expenditure to £4966. The income from investments was £4166 and the annuity expenditure £4458, leaving a deficit for the year on the two Funds of £1754. The committee, faced for the first time with a deficit, are therefore making a special appeal for new subscribers—an appeal which we have warmly endorsed on many previous occasions. The hon. treasurer is Sir Charters Symonds, and the offices of the Fund are at 11, Chandos-street, Cavendish-square, London, W. 1.

READING IN BED.

SLEEP is accepted as part of the nature of things, and yet we know little about it. Theories of physical recuperation do not explain it, for bodily rest is not sleep and cannot take its place. Sleep is a withdrawal of interest from the world, a retreat from conscious life, a shutting off of outer stimuli, and its onset is heralded by a stage in which coherent thought gives way to an undirected flow of ideas, a flow which may escape notice by those happy people to whom sleep comes as surely and regularly as night itself, but may, by a harassing union of vividness and incoherence, present itself as hypnagogic hallucinations that arrest the onset of the deeper loss of consciousness. Or the flow of ideas may be so charged with emotion that interest cannot withdraw from it, and the worries of the day become the sleep-destroying demons of the night. The inability to sleep is a constant symptom of a condition of anxiety—whether due to current trouble in the outer world or arising from a psychopathological cause within the sufferer—and the thoughts that come crowding into the wakeful night add to the feelings of exhaustion and foreboding that mar the following day. But other conditions influence sleep. The essentials of bodily comfort and a moderate degree of mental or physical tiredness aid that pleasant anticipation which is perhaps the surest prelude to sleep, whilst exhaustion may make its onset irresistible. Although to the town worker exercise and open air are wonderful soporifics, yet there is a condition of being too tired to sleep, and insomnia is not always to be overcome by the induction of fatigue. Some time-honoured ways of wooing sleep—counting imaginary sheep is traditional—depend upon forced attention to unemotional matters, and the somniferous effect of some subjects, or even speakers and writers, arises from the same combination; on the other hand, if spontaneous interest is sufficiently aroused wakefulness may result.

These considerations result from the contemplation of a series of light volumes under the title of "The Bedside Library,"¹ which has been planned for reading

¹ London and Toronto: Messrs. J. M. Dent and Sons. Price of each volume, 2s. 6d. cloth; 3s. 6d. leather.

in bed. We need not assume that the aim of reading in bed is always to induce sleep, nor do the publishers say in so many words that the subjects of these dainty books are selected with that aim, but attention is drawn to the absence of contentious subjects, to the soothing appearance of the form of the book, and to the facility of reading and handling it; attributes not distasteful to him who reads in bed because he likes to, but especially attractive to those who seek in the practice a pleasant aid to slumber. To seize and hold expectant attention would defeat this aim; hence we are not surprised to find that, like contentious material, the thrilling and highly emotional finds no part in the series. The only novel is "Cranford" and, delightful as this classic is, the thread of the story is slender and the drowsy reader can readily break off, to renew on the morrow, his acquaintance with the restful personalities of Mrs. Gaskell's creation. "The Golden Book of St. Augustine" follows, too, the golden mean of moderate interest and in its diction is far enough removed from modernity to call for that effort which, not sufficient to perturb, yet suffices to induce relaxation of effort when other conditions favour sleep. The range of subjects in the series is wide enough for most of those who may seek by reading in bed to induce a flow of mildly toned ideas as a stage towards the night's repose.

ANÆSTHESIA FOR REMOVAL OF TONSILS.

THERE are few operations about which so much difference of opinion has been expressed as has been uttered with regard to the removal of the tonsils. No little part of this divergency of opinion centres on the questions of what is the best anæsthetic to use and how it should be given. In this country there is no large support for the use of local anæsthetics at this operation, and controversy has mainly been waged around the respective merits of chloroform and ether and of a deep or a light state of narcosis. At the present time we believe the consensus of expert opinion is for a deep ether anæsthesia in all but the shortest operations. In America, however, the position is different, because local analgesics have been widely used and recommended for tonsillectomy. In a symposium on the question recently instituted by the *Therapeutic Gazette*, of Detroit, we are able to see that opinion among the contributors to the discussion is pretty evenly divided between those who prefer local and those who prefer general methods. Nevertheless, there are several statements made that will, we think, go far to corroborate in their opinion those operators who employ almost entirely general anæsthetics for the operation of removal of the tonsils. For example, it is pointed out that the danger of pneumonia and abscess of the lung is by no means negligible when local anæsthetics are employed. We know of no statistics showing the rate of occurrence of this complication after removal of tonsils during general anæsthesia, but a wide experience assures us that it must be of the greatest rarity. Similarly, deep cervical infection, a very rare sequel to the operation performed here, appears to be not so unusual after the use of local agents. In fact, it is easy to see how, unless great care and skill are exercised, local infiltration in the neighbourhood of a septic tonsil—and, of course, most of those to be removed are septic—very easily gives rise to serious trouble in the form of a local cellulitis or a more general septic poisoning. In answer to this, of course, it might be urged that the avoidance of these undesirable results is as much in the hands of the surgeon as is the avoidance of accident in anæsthesia in the hands of the anæsthetist; that skilled use of injection, in fact, is no more dangerous than skilled use of chloroform. Each method has an inherent possibility of danger that is only repressed by the knowledge and skill of the user of the method. Yet when it comes to reckoning the safety of the method itself, if ether be substituted for chloroform, we imagine that the inherent danger is larger in the case of injection than in that of inhalation. Some would maintain that this is especially the

case if adrenalin is included in the injection. On the other hand, at least one contributor to the Detroit symposium specifically mentions this drug as increasing the safety of injection.

The question of hæmorrhage bulks largely in the opinions expressed. Those who advocate general anæsthetics urge that the efficient control of bleeding is extremely inconvenient, if not impossible, when only local analgesics are used, should the hæmorrhage require ligation of vessels or suture of the pillars. Their opponents argue that bleeding of this degree is so rare, when local agents are used, that how to deal with it need not enter into any argument about the relative results of local and general anæsthesia. With regard to the age of patients, we note that even the ardent supporters of local analgesia do not recommend its use for children. With adults, too, in the case of this as of every other operation, the mentality and general character of the patient must be carefully assessed before he or she is operated on during full consciousness. Here, moreover, the personality and practice of the operator play a predominating part. There is no doubt that the man who is accustomed to operating on conscious patients, and prefers it, can influence favourably the mental attitude of his patients in a way impossible to him who is not perfectly at home with the method. Nevertheless, some patients pay afterwards for the apparent serenity with which they have borne the operation. There are certain subjects who fall obviously into the category of those who should have general rather than local anæsthetics, and there are some of whom the converse is true. The latter, however, appear to be very few. The serious disturbances of the respiratory tract which almost preclude inhalation anæsthesia are rarely present in those for whom the removal of tonsils is deemed advisable. Even if they were, it is probable that a rectal anæsthetic might be preferable to a local one. It is interesting to note in the opinions expressed in favour of general anæsthesia that nitrous oxide followed by ether is a favourite method. This was the case in Great Britain, but has, we believe, largely been superseded by an open method for throat cases.

THE MANUFACTURE OF INSULIN.

As announced in our last issue, the manufacture of insulin in fair quantity has already been achieved in this country, and a few further details of its manufacture may be of interest. The raw material is ox pancreas drawn direct from the slaughter-houses and brought to the factory within an hour or two of slaughter. Great importance is attached to high speed at this stage, because without it the activity of the gland is destroyed by the proteolytic enzymes of the pancreas. The fresh glands, after careful dissection, are extracted by the method of Banting, Best, and Collip with 50 per cent. alcohol, and this extract is precipitated by adding strong alcohol until the alcoholic strength of the mixture is 80 per cent. The liquid is now filtered to remove precipitated enzymes and so forth; during this stage the liquid is kept at a very low temperature, so that the action of the proteolytic enzymes is inhibited. For this purpose the manufacturers have constructed a specially designed cold-room in which a temperature of -5°C . is maintained. The next stage in the manufacture is concentration in a high vacuum at a very low temperature, and subsequently the fat and lipoids are removed by extracting the concentrated liquid. This liquid is now submitted to a further fractional precipitation with alcohol, by which more impurity is removed; after a further filtration, absolute alcohol is added, by which the crude insulin is precipitated. It is thrown down as a nearly white powder, which is washed and dried; at this stage it possesses an activity such that 40–50 mg. represents an average human dose; it still contains, however, over 90 per cent. of separable inert matter. The removal of the latter constitutes the last stage of the purification. The ingenious method employed for this purpose was, as already noted, discovered in

the laboratories of the National Institute for Medical Research, and communicated to the various firms licensed by the Medical Research Council; by its use the activity of the product is increased so that about 3 mg. represents an average human dose. The many stages of purification referred to above have for their object the removal of all substances likely to cause irritation or to have toxic effects; they also greatly enhance the stability of the finished product. The active substance is a very "sensitive" one, and unless minute attention is given throughout the process to the smallest details it is liable to be completely lost. The next stage in preparing insulin for medical use consists in estimating as accurately as possible its physiological activity. This is done by injecting a series of doses into rabbits and determining the blood-sugar before and after administration. Next, a sterile solution has to be made, and since insulin is not thermo-stable, and therefore cannot be sterilised by heat, this is by no means easy, but it is successfully achieved by centrifugalisation and filtration. Finally, the product has to be tested bacteriologically to confirm its sterility and physiologically to confirm its strength by a further determination of its effect on the blood-sugar of a rabbit. It is then issued in sealed capsules or rubber-capped bottles, each cubic centimetre of the contents containing 20 units of insulin.

THYROID FEEDING AND GROWTH.

ENDOCRINOLOGY has been called a modern form of mythology; at whatever point the scientific worker encounters the endocrine gland, be it on the physiological, clinical, or pathological issue, he is confronted with conflicting statements. A vast number of observations have been made on the subject of growth in relation to the secretion of the thyroid gland. By common consent experimental workers appear to have approached this subject by two methods: (1) extirpation of the thyroid gland, and (2) the feeding of animals with thyroid products. In the case of the former large numbers of experiments have been made since the original observations of Raynard. Many of the results appear contradictory, and it is only of recent years that an explanation has been forthcoming by way of the parathyroids. It seems clear that, generally speaking, in those series of animals in which both internal and external parathyroids were removed along with the thyroids death ensued; whilst in those—chiefly herbivora—in which, by accident or design, the parathyroids were spared, death did not result. In such cases, the parathyroids having been spared, thyroidectomy has resulted, in young animals, in a condition closely resembling human cretinism. On the other side of the picture, thyroid feeding has led to equally contradictory results. Schafer's series of experiments with young white rats showed that thyroid feeding stimulated growth; later other observers obtained contrary results and, on the whole, the balance of evidence, in rats at any rate, appears to be that growth stimulation does not follow thyroid feeding. The whole question is, of course, a very intricate one from an experimental point of view, and involves such issues as fat-metabolism, thyroid toxicity, and the inter-relation of thyroid secretion and iodides—the whole subject indeed, which Prof. E. W. MacBride has termed "internal environment."

During the last few years a new stimulus has been given to the study of this subject by a group of workers who have studied both thyroidectomy and thyroid feeding in amphibia, initiated by the work of Gudernatsch¹ on tadpoles. The advantage of working with amphibia is that a definite end-point can be obtained in the process of metamorphosis; in other words, the question can be studied from the two points of view of (1) growth—i.e., "constant assimilation of food and gradual increase in body size up to a constant maximum"; and (2) differentiation—i.e., metamorphosis. Gudernatsch found that thyroid-fed tadpoles

¹ Gudernatsch, J. F.: *Am. Jour. of Anat.*, 1914, xv., 431.

rapidly metamorphosed into "perfect frogs of minute size, pygmy frogs"—that is, differentiation without growth. Since this work was done many experiments have been made on different phases of the problem, much of it of a fascinating character by reason of the clear-cut end-points which the amphibian experiments yield. By no means the least interesting has been the work of J. S. Huxley and L. T. Hogben² on the Axolotl. This animal is sexually mature in the larval form, and reproduces from generation to generation without leaving the water as an adult salamander. These workers, confirming the original work of Jensen and others, have shown that Axolotl can be metamorphosed on thyroid with the production of exophthalmos, but that iodine free of organic combination fails to have this effect. In a more recent communication Hogben³ has gone a stage further, and he describes the technique and results of thyroidectomy in these animals. Out of 20 animals whose thyroids were excised only 1 died directly from the effect of the operation owing to faulty technique. It is interesting to note that in these thyroidectomised animals, as in normals also, injections of anterior lobe of pituitary produced metamorphosis, whereas pituitary feeding failed. The author also transplanted the thyroids of a large sexually mature Axolotl into another medium-sized individual without producing any signs of metamorphosis.

The importance of this recent work is obvious. It has emphasised once again the number of factors which operate in the vital functions of growth and reproduction. It has opened up new possibilities also in the study of the effects—and possibly the standardisation—of endocrine gland products by the use of the lower animals. In the amphibia, as Hogben points out, it is not a question of comparing relative velocities of growth or weights, but of observing an "all-or-nothing" effect, and it should be possible to test commercial endocrine-gland products in this way with greater precision than can be used in clinical administration. On the clinical side the disorders of growth and development may be due to a variety of causes. Dr. Robert Hutchison⁴ has recently shown how important it is to recognise these differences. Thyroid infantilism, for example, is due to a thyroid deficiency setting in some time after birth, or, if it be congenital, is only partial, and, in Hutchison's opinion, reacts well to thyroid medication; whereas the Lorain type of disease or primary infantilism does not react to this drug or apparently to any other endocrine product, and is presumably of different causation.

MENINGITIS, "SEROUS" AND "SEPTIC."

RECENT correspondence in our columns, consequent upon the report by Mr. H. L. Martyn of the successful surgical treatment of a case of septic meningitis, affords an excellent illustration of the pitfalls into which nomenclature may lead us. Mr. Martyn was undoubtedly dealing with a case in which bacteria were present in the whole of the cerebro-spinal fluid system, since they were seen along with pus cells in that fluid obtained by lumbar puncture. Here, therefore, there is no question of a localised infection, and upon the fortunate termination of the case the patient is to be warmly congratulated, whilst the surgeon has obtained a result which may well be never repeated in his life's experience. This condition, with a purulent infected exudate in the cerebro-spinal fluid, is the criterion of septic meningitis. So far we are upon safe ground. When, however, we come to the discussion of what is meant by "serous meningitis" we step straight into the quagmire of nomenclature—a morass which is further encumbered by the presence of a rival entity in "meningism." The way out is to be found by a consideration of the pathological principles governing the spread of septic processes. It is well known that in all forms of suppuration the fluid products diffuse into the adjacent

tissues in advance of the organisms—upon this depends the phenomenon of chemiotaxis and the emigration of leucocytes which may ultimately delimit the focus of disease. Where the anatomical arrangements of the part are suitable, this "sterile suppuration"—to coin a phrase combining contradictory terms—may be seen in a way in which it is not visible in ordinary abscess formation—for example, in the hypopyon which sometimes accompanies corneal ulcers. In the meninges the anatomical arrangements will allow of a similar demonstration, and it is possible for leucocytes, which have emigrated from the blood-vessels under the chemiotactic influence of diffusing toxins derived from local and delimited zones of suppuration, to be carried by currents through the whole of the cerebro-spinal fluid system and to show at lumbar puncture, in the absence of any actual bacterial infection of the general subarachnoid system. It is in this sense that we may have evidence of meningeal infection without septic meningitis in its fully developed form. Low though the resisting power of the meninges is, it is not entirely absent, and it is highly probable that a slight infection with septic organisms, especially where these are of low virulence, may be recovered from, and this apparently has been the result in Mr. Martyn's case. Upon the well-known facts of the development of suppuration Sir William Milligan's statement that in cases of meningitis there is a stage where the exudate is serous, and another where it is purulent, is perfectly correct; no exudate suddenly appears as pus. The transition to the purulent stage, in the average case, however, is very rapid and the results are very serious. It is only where the cause of the irritation is toxic rather than bacterial, or where, if bacterial, the infection is an extremely mild one, that we can visualise a definite stage in which the exudate can be justifiably referred to as serous and drainage is likely to be effective. With regard to meningism, which appears to us to blend inseparably with "serous meningitis," this must also be looked upon as meningeal irritation from a toxic source. The use of these confusing terms is unfortunate, but it has now become consecrated by time; it would be an advantage, however, if "meningism" and "serous meningitis" were used as synonymous with toxic meningitis, and that the term "septic meningitis" should only be used for definite cases of infection of the subarachnoid space by pyogenic organisms.

PREGNANCY COMPLICATED BY PURPURA.

Dr. George Clark Mosher,¹ of Kansas City, has collected 40 cases of pregnancy complicated by purpura, including one which came under his own observation. The variety of purpura encountered in pregnancy is usually of the hæmorrhagic type, characterised by hæmorrhages from the mucous surfaces, petechiæ, and ecchymoses, a remarkably reduced platelet count, prolonged bleeding time, normal coagulation time, and a non-retractile clot, as in the non-gravid woman similarly affected. In pregnancy, however, metrorrhagia is more frequent. Multiparæ between the ages of 22 and 35 are most frequently affected, and the patient is usually in the sixth or seventh month of pregnancy. Purpura in pregnancy is frequently complicated by some infection, but sometimes occurs apart from this cause as the result of toxæmia. The prognosis is very grave. It is only rarely that a patient recovers after going to term, death occurring at or shortly after delivery from hæmorrhage. The outlook is less serious when there is an early abortion. In half the cases the foetus dies in utero, or a few days after birth. Only exceptionally, as in the present case, does it show any hæmorrhages like the mother. As regards treatment no drugs are of any avail. The only remedy consists in transfusion of blood, keeping the platelet count over 10,000. The present case was that of a VI.-para, aged 36. No abnormal hæmorrhages had occurred in any of her previous pregnancies. Painful

purpuric spots appeared in the sixth month of pregnancy on the legs and abdomen, and then gradually affected the whole body. Three weeks later hæmorrhages from the gums and nose began. 10 c.cm. of normal horse serum controlled the loss of blood for three weeks, but then repeated hæmorrhages from the bowels, gums, and nose set in. Horse serum proved ineffective, but the hæmorrhages were partially stopped by transfusion of 350 c.cm. of citrated blood. Through fear of more extensive bleeding labour was induced, and a female infant, weighing 6½ lb., was born and lived 10 hours. Although it seemed strong and well developed, large ecchymoses appeared on its skin wherever it was touched, although there was no loss of blood from the mucous membranes. The mother did not show excessive bleeding after delivery, all the other hæmorrhages ceased after birth of the child, and complete recovery took place.

BRITISH HOSPITALS ASSOCIATION ANNUAL CONFERENCE.

THE annual conference of the British Hospitals Association will be held at the Victoria Station Hotel, Sheffield, on May 31st and June 1st, when Sir Arthur Stanley will preside at the deliberations and the Lord Mayor of Sheffield will welcome delegates. The first business will be to consider the reference from the last annual meeting concerning the establishment of a central fund for the provincial hospitals. Mr. H. J. Waring will then deliver an address on the Future of Voluntary Hospitals from a Medical View-Point, to be followed by a discussion. In the afternoon of the first day of the congress a discussion on Modern Hospital Administration will be opened by Dr. S. S. Goldwater (Mount Sinai Hospital, New York). On June 1st, after a business meeting, Sir Napier Burnett will make a statement on hospital finance, to be followed by an address by Lord Hambleden on Hospital Finance in its Relation to Approved Societies, and a discussion. Various social gatherings have been arranged, including an official dinner to the delegates on May 31st. Many hospitals and convalescent homes in and near Sheffield will be open to delegates in the afternoons. The Sheffield Conference Committee announce that they will arrange to provide private hospitality for such delegates as do not prefer to secure their own hotel accommodation. Official programmes for the conference will shortly be available from the regional secretary, Mr. S. R. Lamb, Sheffield Joint Hospitals' Council, St. Peter's Close, Sheffield.

THE ULTIMATE RESULTS OF GASTRECTOMY FOR CANCER.

THE comparative merits of gastrectomy and gastro-enterostomy for malignant disease of the stomach are carefully weighed in a paper in *Paris Médical* for April 7th by Dr. G. Lion, who backs his arguments by statistics. In the period 1903-1919, 41 of his patients underwent gastrectomy for cancer of the stomach, the operations being performed by various surgeons. There were 16 operative deaths—i.e., a mortality of 39 per cent. Of the 25 who survived the operation, six died within the first year, six within the second year, one lived two years, and another lived two years and a few months after the operation. There remained 11 patients who survived the operation by more than four years, but of these 11 only five were still alive. During the same period 49 patients were treated for cancer of the stomach by gastro-enterostomy. The operation mortality was only 20 per cent.—i.e., approximately half that of gastrectomy. Further, in most cases an appreciable amelioration of the symptoms was obtained. But the duration of this amelioration and of the patient's life was in almost every case very limited, the average being only six to eight months. In the literature of gastro-enterostomy for cancer there have been published

only six convincing cases in which the post-operative survival was a matter of years, and it is doubtful if any patient, in whom the diagnosis of malignant disease was certain, has survived simple gastro-enterostomy by more than five years. On the other hand, among Dr. Lion's 41 cases of gastrectomy there were nine, or 22 per cent., who survived the operation by more than five years. If the operative deaths be excluded, then 44 per cent. survived the operation by more than four years, and 36 per cent. by more than five years. It should also be borne in mind that some of these cases belong to a period when the early diagnosis of malignant disease of the stomach could not be made with the same certainty that it can to-day. With the help of the X rays and other modern methods for the early diagnosis of malignant disease of the stomach, and with improved operative technique, Dr. Lion argues that the late results which he publishes could be considerably improved upon. To the question: Gastrectomy or gastro-enterostomy? his answer is: Gastrectomy in every operable case. He raises another question which may be pertinent in this country as well as in France: Why is the medical profession so shy of the stomach tube? It may often yield information bringing the patient to the surgeon while the disease is still operable, and the risk of making a false passage with a stomach tube is negligible. This cannot be said of the urethral catheter of the use of which few are timid.

COLOURING POISONOUS DRUGS.

IT is stated that the General Medical Council has been invited to express an opinion upon the suggestion that strychnine in future should contain "brilliant green" to an extent that would render it readily recognisable, and it is further proposed that distinctive colouring matter should be added to such commercial products as sheep-dips and weed-killers, with the same object of preventing danger to human life through negligence or criminal intent. It would, no doubt, be desirable in the interest of the patient or dispenser that drugs dangerous to life in excessive quantities, and used in compounding medicines, should be so distinguished that accidental failure to recognise them would become impossible. Such accidents are, however, not common, and a patient might be alarmed at the appearance of a medicine containing a perfectly proper ingredient. In the case of sheep-dips, weed-killers, poisons for vermin, and other substances in common use, criminal trials have shown that poisons such as arsenic can be used with fatal effect, and that their detection may only take place with difficulty when the death of a person poisoned has for some reason excited suspicion. Such suspicion, however, may not arise until it is too late to obtain proof as to how the poison came to be taken, and the form under which it was obtained. How many cases may escape detection altogether is not known. A very vivid and distinctive colouring might deter a poisoner or warn his victim, if it were undisguisable even in minute quantities and highly diluted. It would also, of course, assist in the detection of the cause of death. Whether it would tend to advertise the poison and its efficacy to persons desirous of using it for the purpose of suicide, or to would-be poisoners, who might trust to being able to disguise it, is a question which no doubt will receive consideration.

ATTENTION is called to a comprehensive course on medical hydrology to be held from May 29th to June 4th, a full programme of which will be found in our news columns.

THE Oliver-Sharpey Lectures will be delivered on May 1st and 3rd, at 5 P.M., at the Royal College of Physicians of London, Pall Mall East, by Dr. H. H. Dale, F.R.S. The subject will be the Activity of the Capillary Blood-vessels, and its Relation to Certain Forms of Toxæmia.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

XVII.—THE TREATMENT OF MEASLES.

THE more one sees of this disease the stronger the conviction grows that the most essential agencies in the successful treatment of measles, whether in home or hospital, are fresh air and proper feeding. One cannot fail to be struck with the immense, and usually rapid, improvement which takes place when a child, removed from the stuffy and frequently overcrowded atmosphere of a poor home, is placed under hospital conditions, where in addition to personal cleanliness it meets, perhaps for the first time, with an ample supply of fresh air and suitable feeding, not only in respect of the nature and amount of food, but of the conditions under which it is given. It would seem, therefore, that in the home treatment of measles we should aim at reproducing, as far as possible, the conditions a patient would meet with in hospital.

Ventilation of the Room.

Free ventilation should be secured by means of an open window and a fire, direct draught being avoided as far as can be. Warmth of the atmosphere is more important in measles, especially during the early stage, than in any other infectious fever, with the possible exception of laryngeal diphtheria. The temperature of the room should be kept at about 65° F., or a little over, but should not be allowed to rise above 70°. To secure this degree of warmth, however, the ventilation must not be sacrificed, although it is often difficult to avoid doing so in cold weather, if the means of heating are inadequate. Under these circumstances it is better to concede a few degrees of heat rather than restrict the admission of fresh air, in view of the liability to broncho-pneumonia. The room should be bright and cheery, daylight being freely admitted, but so long as photophobia is present glare should be avoided by partially lowering the blind, and the bed so placed as not to face the window. All superfluous furniture should, of course, be removed and strict attention paid to the cleanliness of the room, as should always be the case when dealing with an infective fever. The bedclothes should be light yet warm, and the patient uncumbered with superfluous blankets. A widespread tendency exists among parents to smother the fevered child in an unnecessary amount of bedclothes, under the utterly wrong impression that by this means he will be prevented from "taking a chill." This, of course, is quite a mistake; he is simply rendered restless and uncomfortable. The right time for heaping on additional blankets is not when the child's temperature is raised above the normal, but after defervescence, when the temperature tends to be subnormal and his resistance to "chill" is lowered by the recent fever. If, owing to free admission of air, the room temperature cannot be raised to the desired level, a flannel or woollen undervest is permissible, otherwise a cotton or linen nightdress next the skin is preferable.

In cases where the appearance of the rash is delayed, as not infrequently happens, additional blankets are valuable in promoting the action of the skin, or the child may be placed for ten minutes in a hot bath and afterwards laid between blankets. Should this not be possible a hot wet pack may be tried instead in cases where the rash fails to develop. The prevalent belief that a "suppressed" rash denotes a liability to pulmonary complication is well founded, and is deserving of careful consideration. The patient should be washed all over once a day with soap and water as a matter of cleanliness, while the surface should be sponged over with fairly hot water several times daily. This tends to bring out the rash, induce sleep, and diminish restlessness.

Toilet of the Eyes, Nose, and Mouth.

In view of the fact that the normal catarrhs of measles are apt to assume undue severity and thus ultimately develop into serious complications, routine attention to the toilet of the eyes, nose, and mouth should be undertaken daily as a measure of prophylaxis. The conjunctival sacs should be flushed out several times a day with warm boric lotion, and the opportunity seized to inspect the eyes in a good light at least once every 24 hours, in order to detect the presence of either ciliary injection or corneal opacity at the earliest moment. The child should be encouraged, and, if practicable, taught to blow its nose at intervals, and if much blocked with mucus it is well gently to irrigate the nares with weak boric solution containing salt, one drachm to the pint, at intervals. This will promote the patient's comfort by keeping the nasal passages clear, and lessen the chance of the middle ear becoming involved by extension.

The condition of the mouth and tongue in measles calls for constant attention on the nurse's part, since they soon become dry and foul if neglected. Our aim should be to keep down oral sepsis as far as possible. Failure in this respect may not only make all the difference in the patient's readiness to take his food, but an unhealthy condition of the mouth may be directly responsible for the occurrence of ulcerative stomatitis, gastro-intestinal disturbance, and possibly broncho-pneumonia. To cleanse the mouth the nurse should carefully wipe out the buccal pouches, gums, and teeth on both sides, floor of the mouth, and surface of the tongue with her index finger sheathed in a thin layer of damp cotton-wool dipped in some antiseptic solution. Chlorine lotion, hydrogen peroxide, 2½ per cent., and Condy's fluid are all of them good for the purpose. The tongue should be finally moistened with glycerine of borax, to which a few drops of lemon-juice have been added. The right time for doing out the mouth is immediately after feeding, though patients will often take their food better if the mouth be cleaned before giving it.

The Diet.

The dietary of the measles patient calls for special care, as is evidenced by the frequent occurrence of diarrhoea at quite an early stage of the illness. This is due to intestinal catarrh, and if not checked may lead to rapid loss of flesh and strength; if it arises in the late eruptive stage, it is apt to prove very intractable. The diet should be chiefly milk, diluted with half its volume of water, or preferably, lime-water, given in small amounts and at frequent intervals. If diarrhoea be present, and the patient very young, the milk may be given citrated or peptonised. Beef-tea or meat-broths are best avoided in measles as a possible source of irritation, though, even if diarrhoea is present, small quantities of meat-juice together with a few drops of brandy may be given with advantage in face of exhaustion.

Treatment of Complications.

In view of the fact that the complications of measles may in almost every instance be regarded as an exaggeration of one of its normal catarrhs, local treatment, if undertaken early, might be expected to prove effective in arresting their development. A tendency to laryngitis will be lessened by steam inhalations, and nothing is more effective in soothing laryngeal irritability, and the persistent cough which attends it, than the inhalation of carbolic acid vapour. Bronchitis of any degree calls for counter-irritation and a cotton-wool jacket. The chest may be rubbed with liniment containing camphor or cajuput oil, turpentine, or some stimulating application, and a simple expectorant mixture containing paregoric and carbonate of ammonia given internally.

Should broncho-pneumonia develop, the same treatment is indicated, but the condition is likely to be more serious and protracted. Linseed meal poultices to the chest are valuable in the early stages, especially in the case of very young children. That

the lives of many young children suffering from the broncho-pneumonia of measles and whooping-cough may be, and often have been, saved by the early application of jacket poultices I am quite convinced, the sceptics notwithstanding. In broncho-pneumonia a liberal supply of nourishment and fresh air is of paramount importance. Plenty of milk, supplemented with Benger's food or sanato-gen, egg flip, beef jelly, or meat-juice, and in most cases a little brandy, are the articles mostly to be relied on. Under the conditions of ventilation described above restlessness and pyrexia are reduced, the appetite is remarkably increased, and recovery expedited, while the liability for the child ultimately to fall a victim to pulmonary tuberculosis is considerably lessened. The good results attending open-air treatment of broncho-pneumonia following measles have been convincingly shown by Dr. Claude Ker of Edinburgh.

Diarrhœa.—The mild gastro-intestinal catarrh, which so often attends measles, is liable to culminate in a severe form of enteritis should the diarrhœa be neglected and the patient be fed injudiciously. If peptonising the milk, or diluting it with lime-water, is not successful in controlling the diarrhœa, even with the help of astringents such as bismuth, catechu, and chalk, and a few drops of tincture of opium, milk should cease to be given, and whey, fortified by white of egg, milk-sugar and, later, a little cream be substituted. Small doses of hyd. cum creta and Dover's powder, given two or three times a day, are useful in some cases, while a starch and opium enema (15 to 20 drops of laudanum in 2 oz. of boiled starch) given after each loose stool is sometimes successful. Washing out the large bowel daily with 1 per cent. boric acid is worth a trial in colitis when the diarrhœa proves intractable.

Severe ulcerative stomatitis is rarely seen nowadays, except in children whose resistance has been lowered by other recent illness. If the ulceration is mild in degree and limited to the free border of the gum, painting the affected surface daily with 2 per cent. nitrate of silver and frequent cleansing of the mouth with a solution of hydrogen peroxide or Condy's fluid will be successful, but in a severe case with sloughing of the tissues, nothing short of free scraping of the diseased surface with a sharp curette and the application of fuming nitric acid under an anæsthetic will prove effective.

Conjunctivitis.—For conjunctivitis of slight degree the daily irrigation with boric lotion may prove sufficient, but if there is much chemosis and the discharge becomes purulent the inner surface of the lids should be painted with nitrate of silver, 10 gr. to the ounce, every other day in addition. Should corneal ulceration threaten, an ointment containing yellow oxide of mercury and atropine must be used, and the eyes efficiently shaded.

Otitis Media.—The occurrence of earache, tenderness on pressure over the external canal, and slight pyrexia denotes otitis media, in which case the application of a large hot fomentation to the side of the head, and frequently renewed, will relieve pain and encourage the appearance of a discharge. Syringing the ear several times a day with warm boric lotion following the instillation of hydrogen peroxide drops will soon clear up the otorrhœa.

Infectivity.—The measles patient, though very infectious in the early stage of the attack, soon loses his infectivity, and may be safely allowed to mix again with others at the expiration of a week, dating from the time at which the rash first made its appearance. It is wise, however, in most cases to keep the patient in bed for ten days or more, in view of the risk of pulmonary complications. No attention need be paid to the occasional presence of peeling.

Disinfection.—A rigorous disinfection of the room after measles is unnecessary, simple cleansing being quite sufficient for safety.

THE NEW ANATOMY BUILDING AT UNIVERSITY COLLEGE, LONDON.

BY PROF. G. ELLIOT SMITH, M.D. SYD.,
F.R.C.P. LOND., F.R.S.

THE erection of the new building for the Department of Anatomy, which also provides an extension for the Department of Physiology, completes the scheme for the development of the building for the Faculty of Medical Sciences which had long been contemplated, the proposal having been first definitely formulated on the initiative of Prof. E. H. Starling in 1907. Funds having become available through the generosity of a number of donors, amongst whom were Sir W. Gwynne Evans, Prof. Plimmer, Dr. Ludwig Mond, and Mr. Thomas Webb, the portion of the Institute to be dedicated to physiology was begun in 1908 and formally opened in 1909 by Lord Haldane. From the outset the new Institute, under the inspiring guidance of Prof. Starling and Sir William Bayliss, attracted students and research workers from all over the world, and it soon became apparent that the available accommodation was not equal to the demand made upon it. The erection of the second portion of the projected Institute of Medical Sciences—viz., that to accommodate the Department of Pharmacology—was rendered possible by the generosity of the late Mr. Andrew Carnegie. The pharmacology building, which adjoins the Institute of Physiology on the east side, was completed in 1912, in accordance with plans drawn up by Prof. A. R. Cushny, and was formally opened by Sir Thomas Barlow.

A site facing Gower-street, adjoining the western end of the Institute of Physiology, was allocated for the third portion of the Institute to accommodate the Department of Anatomy, hitherto most inadequately housed. Before the scheme could be completed the war intervened, but the College did not abandon hope. The war, if it destroyed any chance of the immediate fulfilment of our plans, brought us into closer relations with the academic institutions and medical men of the United States of America. The Rockefeller Foundation was eager to give some striking expression of American friendship to the British Empire, and was also anxious to enlist the help of British medicine in its great schemes for "the promotion of the well-being of mankind throughout the world." The Foundation has already spent large sums in the United States, in South America, and in China for the establishment of schools in which research and the education of medical men should go hand in hand.

The Rockefeller Gift.

At the end of 1919 two representatives of the Rockefeller Foundation, Dr. Wickliffe Rose, General Director of the International Health Board, and Dr. Richard M. Pearce, Adviser in Medical Education to the Foundation, came over to inquire into the methods, problems, and needs of medical education in Europe. The recent establishment, under the stimulus and with the financial help of the Board of Education, at several of the London medical schools of clinical "units" in medicine, surgery, and gynæcology, staffed by whole-time teachers, excited their interest, since the Foundation had already played a large part in the encouragement and endowment of this system of medical education in America. The essential feature in this system is the close coöperation between all departments concerned in the medical curriculum. It is recognised that medicine and surgery cannot advance except in association with the other departments hitherto regarded as more purely scientific, in particular pathology, anatomy, physiology, and biochemistry.

At University College Drs. Rose and Pearce found a hospital which had been founded for the express purpose of medical education. They found also active and well-equipped institutes for the study of some

branches of medical science and definite plans for the completion of a whole scheme of medical education as soon as the necessary funds were available. Thus, in the College there was fair provision for physiology, pharmacology, and biochemistry, but no proper facilities for teaching and research in anatomy, embryology, and histology. In the clinical subjects of the curriculum, while medicine and surgery were represented by whole-time professors at University College Hospital Medical School, there was a lack of beds devoted entirely to the work of these units, and the accommodation for research into the chemistry of disease was deficient; there was no adequate provision for scientific investigation and teaching of midwifery and the diseases of women. Plans for the remedying of these gaps in the scheme were ready; the only thing necessary was money. The representatives reported favourably on this scheme for the creation of a complete and scientifically equipped School of Medicine to the Rockefeller Foundation. As a result the Foundation decided not only to place at the disposal of University College sufficient funds for the realisation of the scheme formulated in 1907, but also to provide the additional endowment required to maintain the increase in staff which the scheme entailed. At the same time the Rockefeller Foundation made an even larger gift to University College Hospital Medical School for the promotion of the work of the clinical units.

Reform in the Teaching of Anatomy.

Histology.—It is appropriate that the attempt to institute radical reforms in the teaching of anatomy and in the provision of facilities for research should be made in University College. Paradoxical as it may appear, the reforming zeal of Prof. Sharpey at this College 70 years ago had as one of its ultimate results the crippling of anatomical effort in England, and it is proper that the College which created a physiology so vigorous as to take to itself the more vital and progressive parts of anatomy should be the institution to right this ancient wrong by restoring to anatomy the opportunities for teaching and research in histology and practical embryology, and for the experimental study of the factors that influence growth and development.

The structure of the nervous system, its developmental history, and the connexions displayed by degeneration and experiment are all subjects which should be studied as one connected whole in the Department of Anatomy; and if the complexities of the nervous system are to make any intelligent impression upon students, the functional significance of the arrangements must be discussed and the effects of damage to the nervous system must be used, not with any pretence of teaching the student clinical medicine, but in order to give him some satisfying explanation of a complex and otherwise unintelligible mechanism. It is necessary, then, in any properly equipped institute of anatomy, to provide a neurological department equipped with sets of slides of adult human and embryonic material and of the brains of other vertebrates, and with laboratories for the experimental study of the results of degeneration.

Experimental Work.—It is an essential part of the work of a Department of Anatomy that it should carry on experimental investigations of the factors which influence growth and development and of the causation of anomalies and monstrosities. Such researches have led to results of great importance in exposing the underlying principles of development as well as in explaining the causation of pathological conditions. The equipment of laboratories for such experimental work is therefore a necessary part of the scheme.

X Rays.—The knowledge of the structure of the living body that can be acquired by the use of the X rays is becoming increasingly important in the study of anatomy. At present a student is called upon to interpret radiograms long after he has left the Department of Anatomy, when his familiarity with the relations of the structures has grown dim. The proper time to acquire an understanding of X ray appearances is when the student is actually studying the things of

which the X rays cast shadows, and such studies also teach him his anatomy. The equipment of a Department of Radiology opens up a promising field of anatomical research, which will become increasingly fruitful as the technique of radiography is improved.

A Scheme of Coöperation.

The completion of the building for these three closely allied sciences of anatomy, physiology, and pharmacology is the expression of a far-reaching scheme of coöperation, involving, on the one hand, the closer correlation of teaching and research in these sciences, and on the other the linking up of the work done in the Faculty of Medical Sciences in the College with that done in the Medical School of the Hospital. Moreover, the building is a permanent symbol of the bond that unites us in a common aim with the Medical Schools of America and with the Rockefeller Foundation. The new anatomy building is linked by means of a tunnel passing under Gower-street with the Medical School of University College Hospital, and it is anticipated that this physical avenue of communication will facilitate a freer intercourse between each set of workers to their mutual benefit. The extension of the Department of Physiology affords ampler provision for teaching and research in experimental physiology, and makes it possible for Prof. Starling to remain in the College as Foulerton Research Professor of the Royal Society, even though he relinquishes the Jodrell Chair of Physiology and the Directorship of the Institute which he created.

The Rockefeller endowment has made it possible not only to create a University Chair of Biochemistry, but also to increase the accommodation allotted to this subject. Training will now be provided not only for students of medicine, but also for biochemists, who are in constant demand in research and industry. For these a definite curriculum has been devised.

THE THIRTY-FIFTH CONGRESS OF INTERNAL MEDICINE AT VIENNA.

THE German Society of Internal Medicine, perhaps the most important of all German medical corporations, meets every second year at Wiesbaden, and each alternate year in some other German or Austrian city. This year the place of meeting was Vienna; the Congress, held during the week April 8th to 14th, was the first real international medical assembly in the city since 1913. The attendance numbered more than 1400 medical men, including representatives of the Scandinavian States, Italy, Spain, Russia, Egypt, Japan, China, Canada, and the German-speaking countries. Prof. Karl Wenckebach, well known for his researches in the pathology of the heart, presided over the Congress, of which the transactions were divided into three large groups: Encephalitis lethargica, with its concomitant conditions; hypertension; and disorders of internal secretion. In his introductory address Prof. Wenckebach discussed the relation between the artist and the scientist. Both, he said, are gifted with fancy and observation, both produce results obtained by a combination of mental labour and intuition, and varying according to the proportion of these elements. Observations on children show that the latter possess to a remarkable degree the ability to perceive the characteristic traits of an object. Similar conditions prevail with primitive man, who possesses the same power, as prehistoric cave-drawings have proved; but with the increase of conscious knowledge this power of perception is lost, both in the individual child and in the race. "Knowledge displaces sight," except in a small minority of people; the latter, who retain their congenital gifts, are the artists and idiots. In medicine it is important to observe, without paying too much attention to knowledge alone. According to the present method of medical study, the student must acquire a great deal of knowledge in a very short time, and must believe what others tell him. Prof. Wenckebach urged that

the student might be encouraged to form his own opinion, based on sound knowledge of fundamental principles, and to stay longer than the statutory five years in hospitals and wards. Careful observation of the subject should be the basis of instruction, to enable the doctor, like the artist, to teach himself.

Encephalitis Lethargica.

Prof. K. Economo (Vienna), one of the first men to describe encephalitis lethargica, opened the discussion on this disease. "Sleepy sickness," he said, was first described in 1872 at Tübingen, and in 1890 similar cases were reported from Italy after an epidemic of influenza; in the winter of 1916-17, in Vienna, there occurred about 50 cases of what was recognised by him to be an independent disease, manifested by a tendency to protracted sleep, with marked squint. The condition lasted several weeks or months; about 30 per cent. of those affected were cured; an equal proportion died, whilst the rest remained permanent invalids. Investigations showed the presence of certain bacteria in the brain; Doerr and Levaditi found that these bacteria were filtrable and transmissible to the cornea of rabbits, where they produced conditions very similar to those obtained by infection with the contents of the ordinary herpes vesicles. It seemed likely that the aetiology of herpes and that of encephalitis lethargica were identical, but in the latter disease the virulence was much greater for reasons still unknown. Transmission probably took place through the air, by way of the naso-pharynx. A very few contacts were infectious (4 per cent.). Treatment against the encephalitic processes could be satisfactory in the early stages only. Intravenous injection of large doses of iodine gave good results in acute cases; chronic cases were still resistant to treatment. The clinical manifestations were sometimes more choreic, terminating in cataleptic conditions, with peculiar disturbances of will or intention. Observations of these conditions proved the function of sleep and awakening to be controlled by a certain focus in the brain very near the centre for ocular movement; encephalitic lesions of this focus produced changes in the rhythm and duration of sleep—e.g., months of daylight sleep. The cataleptic conditions were traceable to an organic lesion of the ganglia situated between the optic thalamus, the corpora geniculata, and the pineal body. The chief interest of these manifestations was centred on the fact that "will" (intention) no longer appeared to be entirely a result of psychical processes. Cataleptic conditions were formerly regarded as symptoms of psychic disease, but it was now found that a patient in such a condition had a well-localised organic lesion in the borderland between the ganglia connected with sensations and movements. The explanation of certain neuroses and psychoses, formerly thought to be due to psychic repression, had thus been placed on a new anatomical basis.

A second paper on the same subject was read by Prof. M. Nonne (Hamburg), who dealt chiefly with the clinical picture of the disease. He had examined and observed 162 cases, and was satisfied that between the acute and chronic stages a normal stage might intervene lasting up to three or four years. Few cases were definitely cured; the after-effects were more or less marked in nearly all patients. Prof. Nonne agreed with Prof. Economo as regards the aetiological factor, but suggested the possibility of a special neurotrophic toxin, similar to that found in meta-syphilitic processes. He thought that the frequent disturbances of the function of the liver might be explained by assuming a lesion of a brain-centre regulating the functions of this organ. The manifestations of chronic encephalitis could be placed in three groups: In the first psychic symptoms were prevalent; in the second the disturbances were centred in the organs of movement; and in the third metabolism was chiefly affected. Very often nothing was observed but a change of personality, without marked intellectual difference. The study of the pathology of this disease had greatly influenced current views as

regards the diseases of the nervous system; it had given useful clues as to the function of the nucleus caudatus and nucleus lenticulatus, parts of the brain which controlled the voluntary innervation of single groups of muscles. The slightest conscious voluntary innervation of a given group of muscles required an involuntary "synergistic" innervation of numerous other muscles; chronic encephalitis lethargica, however, disturbed this innervation control, with the resulting characteristic "cataleptic" conditions (Parkinson). The tonus of the muscles, and the attitudes and positions of the joints, were regulated, apart from conscious volition, in the ganglia which are chiefly affected by the inflammations of encephalitis lethargica. The metabolic disturbances so often noted after the attack pointed to inflammation of the controlling brain-centres; these were marked adiposity with nervous disturbances, and extreme emaciation without disease, as well as with diabetes mellitus and insipidus. (Prof. Nonne had observed a case with an output of over 20 litres, or 40 pints, a day.)

The Laws of Heredity.

An animated discussion followed these two reports, during which many speakers expressed agreement with the ideas set forth. Amongst other papers may be mentioned that of Prof. A. Pick (Prague), who discussed the problems of "heredity in mankind." The laws of Mendel, he said, were valid in this connexion, but it was extremely difficult to obtain suitable material for study, as experimentation was hardly possible. Satisfactory observations were made on twins from the same ovum. He had seen and read of only 30 cases in 12 years of hereditary diseases in such twins; and even normal traits (finger-prints) had been observed by very few workers. As a rule, such observations had only been reported where twins were attacked synchronously by the same disease (e.g., epileptic seizures, asthma, diabetes, or infectious disease with very similar course), whilst recessive diseases, which would give a much better insight into the laws of heredity, were rarely reported. It was important to remember that whilst twins from the same ovum were always of the same sex, only 25 per cent. of the same sex were from the same ovum. Yet in a case of colour-blindness and in another one of alkaptonuria, in absolutely certain twins of the same ovum, only one twin was diseased. As regards the variation of dominant symptoms, convincing data could rarely be obtained; Prof. Pick could show, however, that in some families migraine, Graves's disease, or asthma, from which one of the parents suffered, was transmitted to the offspring in such a way that the child strongly resembling the diseased parent was much earlier affected by it than the child resembling the healthy parent; the latter child, indeed, was often only affected after the age of 50 years. For the study of such problems, it was suggested that family histories should be collected by family physicians, and that a central institute for pedigrees and family histories should be called into existence.

Surgical Treatment of Angina Pectoris.

Prof. Wenckebach described Prof. H. Eppinger's experiments at Vienna, in which angina pectoris was treated by division of the depressor nerve of the heart. Up till the present the operation has only been done in six cases and the results have been satisfactory. It is based on the researches of Spiegel, who found that there existed a certain type of transmission of pain which he called "Gefässschmerz" (pain of the blood-vessels). The technique of this operation is not yet sufficiently perfected to be generally encouraged. Dr. Torney (Budapest) recommended the injection of cardiac remedies direct into the aorta, especially of adrenalin in cases of collapse. Prof. H. E. Hering (Cologne), Prof. E. Edens (St. Blasien), and Prof. Hediger (Zürich) read papers on cardiac pathology.

Hungarian physicians presented a series of papers on the process of digestion; their researches showed that mastication only influenced the emptying of the stomach in so far as it changed the consistency of the food ingested, which was evacuated according to its

chemical constitution; the carbohydrates were emptied first, the fats last. Great interest was evoked by the paper by Dr. W. Stern (Vienna) on voice-production in patients on whom laryngectomy had been performed. He showed three patients of this kind, who had been taught to use their stomach as bellows for producing an excellent voice in the pharynx. They had learned to swallow large quantities of air and to expel it by using the abdominal muscles, like ventriloquists. This work is important in connexion with the advisability of total laryngectomy in laryngeal cancer.

(To be concluded.)

BUDAPEST.

(FROM OUR OWN CORRESPONDENT.)

The "Half-Deaf" Club.

ABOUT two years ago a school was opened for the partially deaf, in the otological section of the St. John's Hospital, Budapest. It is the experience of teachers of the deaf that the partially deaf can be cured, in the sense that they can be trained to compensate for their disability, but that for this purpose they must be entirely separated from the deaf-mutes. The Ministry of Public Instruction and the city council of Budapest coöperated in the organisation of this school, the Ministry selecting teachers from the deaf-mutes' institutions and the city giving the necessary premises. At present 45 partially deaf children attend the school. There are also courses for adults, and all instruction is free. I have visited one of these schools and heard a lesson given to adults. The teacher narrated his experiences gained on a journey to Turkey, and the partially deaf pupils repeated his words without error. They could not understand single more difficult words, but the teacher wrote the latter on a blackboard, and the pupils rapidly learned to lip-read them. Two teachers sat among the students, and explained the more difficult expressions. The director of the school told me that the course for adults lasts three months; the first course is about to terminate at the present time. One student is a judge, entirely deaf, but now able to lip-read any person's speech without fail. After the course care is taken to maintain contact with students by means of the "Half-deaf" Club, where weekly lectures and concerts are held. There are similar clubs in Berlin and Vienna. In all there are about 14,000 partially deaf persons in Budapest, and many of these have notified their intention to attend the courses.

"Lithia" Waters in Hungary.

Hungary is well known to be very rich in mineral waters; the country may be said to supply the world with aperient waters, and in addition to them has excellent lithia waters. The owners of the springs cannot, however, afford modern machinery for bottling, &c. Several new springs have lately been discovered, all containing more or less lithia; but the term "lithia water" is now too freely used in Hungary and neighbouring countries, waters which contain the merest trace being advertised under its name. This state of affairs is due to the fact that the springs containing lithia in abundance were almost all in those parts of Old Hungary separated from it by the Treaty of Versailles. This fact necessitates legislation to circumscribe the meaning of the word "lithia"; the definition given, in a memorandum prepared to that end, contains the following statement: "This element, as is generally known, occurs in many natural mineral waters in the form of hydrocarbonate and chlorate of lithia, but quantitatively it never forms the chief constituent of these waters. If, however, the carbonate of lithia can be shown by analysis to be present in a quantity of 2 to 3 cg. in one litre of water, this fact may be mentioned in the analytical report for its characterisation and for the estimation of its therapeutic value,

just as mention is made of the fact that a water contains iodine, bromine, &c. This fact alone, however, does not constitute the value of a mineral water, because the therapeutic value and action of natural mineral water are manifested not only in the several constituents present in minute quantities, but depend on all the constituents as well as on their relation to each other. To-day it is generally accepted that every mineral water must be regarded as a separate compound, for two absolutely similar waters cannot be found; consequently, the action of two mineral waters cannot be equal. If this principle were rigorously applied, the action of every mineral water should be separately tested. If, therefore, a certain mineral water contains lithia among other constituents, it is not proper to stress the presence of this one constituent and call it a lithia water. In order to prevent the misuse of this name it would be useful to have a legally protected standard of the amount of lithia required before the name may be employed."

April 10th.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Comdr. L. E. Dartnell has been placed on the Retd. List with rank of Surg. Capt.

Surg. Comdr. C. H. L. Petch has been placed on the Retd. List at own request. —

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. W. J. Waters retires on ret. pay.

Capt. C. R. Dudgeon retires receiving a gratuity, and is granted the rank of Maj.

Capt. W. T. G. Boul (late R.A.M.C., Spec. Res.) to be Capt.

Lt. R. K. Nisbet to be Capt. (prov.).

General Hospitals: The undermentioned having attained the age limit are retired, and retain their rank except where otherwise stated: Lt.-Cols. C. P. Childe (Bt. Col.), E. L. Fox, G. G. Sparrow, H. W. Shettle, J. R. S. Robertson, J. Kyffin, and C. F. Routh; Maj. T. A. M. Forde (Bt. Lt.-Col.), J. R. Keele, W. P. Purvis, H. P. Ward, R. A. Dove, W. C. Wilson, and G. F. Aldous; Capt. G. C. Sandford (granted the rank of Maj.), C. L. Lander (granted the rank of Lt.-Col.), E. G. S. Saunders, W. C. Hamilton, T. Horton, G. A. Roberts, E. R. Clarke, F. E. Price, S. Goss, W. P. McEldowney, J. T. M. McDougall, M. D. Wood, H. L. Driver, and W. Carling.

Capt. G. P. Mills relinquishes his commn. and is granted the rank of Maj.

Sanitary Service: The undermentioned officers relinquish their commns. and retain their rank: Lt.-Cols. Sir A. Newsholme, W. Collingridge, and M. Hay; Maj. S. Barwise, P. Boobyer, H. Handford, E. W. Hope, T. W. J. Kelly, J. Niven, H. C. Pattin, A. E. Parmewan, W. H. Symons, J. S. Tew, J. C. Thresh, L. C. Parkes, W. J. Howarth, J. Murray, A. M. N. Pringle, H. Scurfield, and D. Forbes; Capt. L. M. Bowen-Jones, W. F. Brown, G. H. Carrington, F. J. H. Coutts, J. H. C. Crocker, J. Dawson, A. J. Duncan, E. T. Fison, J. T. Graham, T. W. Graves, A. J. Hall, J. A. Hislop, R. Jones, A. Ledingham, W. C. Lewis, J. D. McCrindle, C. R. Macdonald, A. J. McGregor, W. Mackie, A. C. Munro, J. T. C. Nash, M. Paterson, H. Peck, G. Peterkin, F. B. W. Phillips, J. T. Prangnell, E. W. Rees, Jones, A. Robb, T. Robinson, J. M. Ross, T. Rutherford, E. H. Snell, F. E. Streeten, C. Templeman, A. E. Thomas, J. P. Watt, J. H. Williams, J. T. Wilson, R. M. Yule, A. B. Dunne, T. E. Francis, J. J. Buchan, and F. J. Allan.

ARMY RESERVE OF OFFICERS.

Capt. S. Pinion, late R.A.M.C., to be Capt.

TERRITORIAL ARMY.

Lt.-Col. G. A. Troup, from T.A. Res., to be Col. and Asst. Dir. of Med. Servs., 54th (E. Angl.) Div., T.A.

ROYAL AIR FORCE.

The undermentioned are granted permanent commissions as Flight Lts.: J. R. Crolus and J. M. A. Costello.

C. A. Meaden is granted a temporary commission as a Flight Lt.

INDIAN MEDICAL SERVICE.

Col. J. Jackson to be Maj.-Genl.

Capt. Govind Shivram Mandlik relinquishes his temp. commn. and is permitted to retain the rank of Capt.

THE TEACHING OF OBSTETRICS AND GYNÆCOLOGY.

REPORT ON EXISTING ARRANGEMENTS.

Dr. Janet Campbell's report¹ on the arrangements now in vogue for teaching obstetrics and gynæcology in the medical schools of Great Britain is part of a larger inquiry into the causes and prevention of maternal mortality, the results of which are to be made public later. The first necessity of an efficient midwifery service, as Sir George Newman remarks in a prefatory note, is the training of the medical practitioner. The report is divided into three parts. First, notes are given of the facilities provided by 24 medical schools, including 12 in London, seven provincial English universities, four Scottish universities, and the Welsh National Medical School. Secondly, Dr. Campbell makes observations upon the working of these arrangements and the organisation of the educational facilities. And thirdly, conclusions and recommendations are set down which emerge as a result of Dr. Campbell's knowledge and experience in this and other countries.

Provision of Maternity Beds.

The provision of such beds in the teaching hospitals of London is, Dr. Campbell reminds us, a recent development, initiated primarily to meet the needs of students from such universities as Oxford and Cambridge (where in-patient maternity experience is a requirement), but extended because its value to all students has become more clearly appreciated.

In 1906 only two hospitals in London with medical schools possessed lying-in wards, and these were not used for teaching students. Certain hospitals, for example, Charing Cross, St. George's, and Westminster, have still no maternity beds, though such provision is under consideration, and the first two hospitals will probably have maternity wards at an early date. In others the number of beds varies from seven (St. Mary's), eight (University), and nine (London Hospital) to 17 (St. Bartholomew's), 21 (St. Thomas's), 24 (King's College), and 40 belonging to the Royal Free Clinical Unit. All these beds are not wholly at the service of medical students, for to some (e.g., London and Guy's) pupil midwives have a prior claim. Others are divided more or less equally between students and pupils (e.g., St. Thomas's), but the advantage of the medical school being in direct control of both beds and extern district is very great from the point of view of teaching.

In most cases arrangements are made for the students to reside at or near the hospital while taking their midwifery practice, and this should be an invariable rule. The time seems to have come for the teaching hospitals in London to reconsider their accommodation for maternity cases. In Scotland and in the provinces instruction in practical midwifery is usually less closely associated with the university and medical school. The general hospitals used for clinical teaching have no maternity beds (except the Royal Infirmary and General Hospital, Bristol, and the Queen's Hospital, Birmingham), and most students take their midwifery, intern and extern, at a maternity hospital which is also a training school for midwives and over which the university may have little or no direct control.

Maternity hospitals in Aberdeen and Dundee are under the direct supervision of the professors of midwifery, but students compete with pupil midwives, and the number of cases is inadequate for both. The professors of midwifery in Glasgow have no direct control of the maternity hospital. In Edinburgh the maternity hospital is in various respects admittedly unsatisfactory, but the professor, as ex-officio senior physician, is responsible for the general medical management and has access at all times for teaching. In Newcastle the maternity hospital is extremely inadequate, but new premises are about to be provided; the professor exercises general supervision, and there are sufficient cases. In Manchester, St. Mary's Hospitals with 58 maternity beds

are available. In Sheffield there is the Jessop, with 24 maternity beds. In Leeds the Maternity Hospital has 75 beds, but is overcrowded, and the professor is merely one member of the staff, with no ex-officio duties or privileges. At Bristol there are 24 beds at the Royal Infirmary, and 22 (midwifery and gynæcological) at the General. At Birmingham there are three maternity beds at the Queen's, and students are permitted to observe the practice at the Maternity Hospital. At Liverpool there is the Maternity Hospital, which is largely used for pupil midwives; there are five ante-natal beds at the Royal Infirmary, which will shortly be increased by about 20 maternity beds, under the professor.

Pre-Maternity Clinics.

Originating in the somewhat casual arrangements for "booking" prospective maternity patients such ante-natal clinics are rapidly becoming an important branch of the out-patient department. A pioneer centre is that established by the late Dr. J. W. Ballantyne in connexion with the Edinburgh Maternity Hospital, which is now maintained by the local authority as part of the public health activity of the city. The ante-natal clinic at the London Hospital is an example of a recently established centre where the work has become highly developed. At some maternity hospitals the extension of pre-maternal supervision has been hampered by lack of accommodation, but a centre of some kind has proved practicable everywhere. Special arrangements for social service in connexion with ante-natal work are made by the almoner's department at St. Thomas's, the London, and the Royal Free Hospitals and elsewhere. Pre-maternal supervision offers the most promising field for true preventive work in midwifery; it gives opportunity for the investigation of abortions and stillbirths, and it affords the most hopeful means of reducing the heavy mortality of the newly-born which occurs during the first days and weeks of life, a death-rate which has scarcely been touched by the ordinary methods of infant welfare. It may be hoped that post-natal supervision will invariably be added, and that patients will learn to come for examination at least once after the confinement. The post-natal clinic is one of the best instruments of preventive gynæcology. Such a clinic has recently been established at the Royal Free Hospital.

Recommendations.

The principal factors needed to bring the arrangements for teaching midwifery into a position comparable with that of other clinical subjects of the medical curriculum are set out by Dr. Campbell in a concluding section.

Adequate Time.—Where necessary, the curriculum might properly be modified so as to provide a minimum period of three months' whole-time for the study of gynæcology and obstetrics, including the care and management of infancy, to which, whenever practicable, a further period of one month for intern and extern midwifery should be added; this period to be extended when the Resolutions of the General Medical Council come fully into operation.

A Sufficient Number of Maternity Beds to enable all Students to Obtain Suitable In-patient Practice.—Few hospitals attached to medical schools possess sufficient maternity beds to enable the students to secure the minimum amount of in-patient experience recommended by the General Medical Council—namely, the personal delivery of five patients under supervision—and the maternity hospitals which accept medical students are seldom able in existing circumstances to make adequate provision for their training. It is generally agreed that the only way in which a student can be given a clear and correct conception of the principles and practice of clinical midwifery is by means of systematic instruction in the lying-in ward. It is, therefore, most desirable that the authorities of the medical schools should carefully consider how the necessary maternity beds can be made available for teaching purposes, whether by a re-allocation of existing beds, by the addition of new beds to the hospital, or by coming to an arrangement with a maternity institution elsewhere. In-patient practice should be supplemented by work on the midwifery district only when the student has sufficient knowledge of the technique of delivery.

Systematic Instruction in Ante- and Post-natal Supervision for all Students.—Until recent years the care of the mother before and after parturition has received relatively little attention. Pre-natal care, which includes suitable physical examination and the supervision of the general health

¹ Ministry of Health. Reports on Public Health and Medical Subjects. No. 15. Notes on the Arrangements for Teaching of Obstetrics and Gynæcology in the Medical Schools. By Janet M. Campbell, M.D., M.S., Senior Medical Officer for Maternity and Child Welfare. H.M. Stationery Office. 1s. 3d.

throughout pregnancy, is the most effective means we have, first, of eliminating the element of unexpectedness, which leads to a large proportion of the disasters in midwifery practice, by enabling operative measures to be avoided or carried out under pre-determined conditions; and secondly, of applying treatment for constitutional maladies—e.g., syphilis, the toxæmias of pregnancy—which, if neglected, exercise a harmful influence upon the pregnancy. In such ways lives of both mothers and children may be saved, and the injuries which often follow emergency midwifery may be prevented. Post-natal examination is important in order that pathological sequelæ of parturition not previously observed may be promptly recognised and rectified.

Instruction in the Theory and Practice of Midwifery, by means of systematic lectures, clinical demonstrations, the ante-natal clinic, the use of dummy and foetus, and attendance on the practice of a maternity hospital. A considerable part of this teaching may usefully be taken before the student commences his practical midwifery, so that he is in a position to obtain the greatest value from the experience he gains in delivering his own cases.

Instruction in Clinical Midwifery by a Teacher of Experience.—It is essential that the medical student should be trained in the management of normal labour no less carefully than the pupil midwife. Only so can he learn to recognise and appreciate the significance of abnormal conditions when they arise, and unless he is thoroughly familiar with the varying course which a normal case may pursue, he may easily become unduly alarmed at unexpected delay and inclined too readily to invoke the aid of operative modes of delivery. In studying the treatment of difficult labour he should learn to give due weight to the added risks inseparable from operative procedure, and the importance of avoiding artificial methods of delivery as far as practicable.

The Recognition and Treatment of Puerperal Infection.—The student should be taught the various manifestations of puerperal infection and the far-reaching effects which even a relatively mild degree of sepsis may have upon the future health of the patient. He should not only understand the clinical aspect of such cases, but the danger to the community which may follow, and the part the doctor or midwife may unwittingly play in spreading infection. He should realise the importance of notifying puerperal infection, no matter how slight, and the value of the assistance which the medical officer of health of the district to which the patient belongs is able to render in regard to nursing or isolation. Similarly the student should receive definite teaching as to the onset, course, and treatment of ophthalmia neonatorum, and the disastrous results the smallest neglect may have upon the eyes; here, also, he should learn the importance of co-operation with the local authority, and the same applies to the treatment of venereal disease associated with pregnancy.

The Effective Control of the teaching of practical midwifery by the medical school or faculty so that each student may be sure of delivery personally at least the required minimum number of midwifery cases. Two things seem to be necessary—namely, exercise of the student's own responsibility in delivery, and such modifications in the examination as will stimulate interest, good workmanship, and sound practice.

Medical Staff.—The department of obstetrics and gynaecology should be staffed in such a way as to admit of the two subjects being taken as integral parts of one whole, so that the student may realise how, on the one hand, the pathological sequelæ of childbirth take their place among "diseases of women" and, on the other, the effect which gynaecological maladies may exercise upon pregnancy and labour. Further, the staff organisation should provide for instruction in the elements of clinical midwifery being given by an experienced teacher; at the present time much of the teaching and responsibility for practical work still remains in the hands of junior and temporary members of the staff who have insufficient knowledge both of midwifery and of the educational methods of presenting the subject.

Conclusion.

Dr. Campbell ends on a note of hope. So much progress, she writes, has already been made towards the organisation of wholly satisfactory and efficient education in midwifery and gynaecology, and the value to individual patients and to the community of an adequate midwifery service is becoming so plainly recognised, that we may look forward hopefully and with confidence to a time not far distant when all practitioners will not only be well and thoroughly trained in this branch of the medical curriculum, but will possess the knowledge and sympathy needed to bring about a mutually advantageous partnership with local authorities and the State. For without such co-operation the most fruitful results of public and voluntary effort for the welfare of mothers and children cannot be obtained.

"Audi alteram partem."

SERUM DOSAGE IN DIPHTHERIA.

To the Editor of THE LANCET.

SIR,—That the recent discussion regarding the method of administration and the correct dosage of diphtheria antitoxin should have been called for at all fills me with feelings akin to despair. I had believed that, when the Ministry of Health had arrived at the point of advising practitioners to use an 8000-unit initial dose, the teaching of many years had at last received its hallmark of approval. Now that great authority Dr. Claude Ker has doubts about it. I feel strongly that if Dr. Ker's life had been spent in the East-end of London instead of in the northern metropolis he would have no doubts. It is evident, as Dr. Peters says, that diphtheria at Colinton has no comparison in toxicity with either East-end or, for the matter of that, Bristol diphtheria; and it follows that if, in Edinburgh, the disease is less toxic, the terrible results of delay in diagnosis and in administration of the remedy are there less apparent. When I joined the late Dr. J. Biernacki at Plaistow in 1906 the 8000-unit dose was the usual. Delayed diagnosis and hence tardy admission to hospital were such that very rarely could we feel safe in giving less. We taught the students the importance of large initial doses then, and my experience since those days has only served to increase manifold my faith in them. It is, indeed, a calamity that after so many years of teaching, when one has worked men up to giving large doses, the ground should be taken from under one's feet in this way. I have seen diphtheria in several parts of the country, but I still believe that in the East-end it is toxic as it is nowhere else. But in teaching dosage to students who are going to practise one cannot safely take into consideration either this, or such a case as Dr. Ker's case of convalescent scarlet fever, which he saw almost at the moment of onset. One must teach broad facts, and leave the exceptions to look after themselves when one is teaching juniors. Post-graduate work in fevers—more's the pity—is not often called for.

The other point is the question of intravenous medication. I have the typed copy of Dr. Biernacki's lecture on laryngeal diphtheria, 1906, by me as I write. "At Plaistow Hospital the antitoxin is given by preference intravenously, but a selected serum is then advisable." One might add that the serum should also be warmed before use. During the whole period of over two years in which I followed Dr. Muir as deputy medical superintendent at Plaistow I gave many hundreds of direct intravenous injections in the more toxic cases. I entirely agree that an anæsthetic is not to be thought of, nor is dissecting out of the vein. But that time—I put it at eight hours—is gained by this method is, I think, undeniable, and I have ever since taught it to students, as I taught it at Plaistow with Dr. Biernacki's approval. It is not as a rule a difficult matter in children over 3 years of age if one has an assistant accustomed to holding the arm. Manual constriction of the arm by her instead of by tourniquet is the method par excellence. I have never used any other form of bringing up the vein in children. If it failed one might try the other arm; if that failed also, one then gave the serum subcutaneously. Anaphylactic phenomena of any severity were never seen by us.

As I emphasised in an (unpublished) address before the Bolton Medical Society some years ago, it is a noticeable feature at the present time when taking the family history of young adult lives of good class for life insurance purposes, how often one is told of the death of a brother or sister of the proposer during childhood from diphtheria. That this should still be the case after antitoxin has been the accepted remedy for so many years shows that unnecessary

deaths are occurring. These cases have been in a class of person who are observant and who call in the doctor at the first sign of anything going wrong with a child. Earlier diagnosis, without waiting for results of swabs, and doses which take into account not only the size of the patch or patches, but the duration of the disease (how is it Dr. Ker does not mention this in his "scales of dosage"?) and the site of the patches must still be forcibly taught.

One thing more. Teach parents that the thermometer is not to be the only reason for calling in the doctor; for these calamities occur in well-to-do folk who are inclined to let the thermometer decide as to whether the doctor shall be summoned or not. And yet, as all fever men know, the temperature at the onset of diphtheria may be subnormal, and the child, or even adult, may make no complaint of sore-throat.—I am, Sir, yours faithfully,

FRANK E. TYLECOTE,

Senior Assistant Physician, Manchester Royal Infirmary.

April 17th, 1923.

To the Editor of THE LANCET.

SIR,—In reply to the various criticisms on my views regarding serum dosage I admit that Dr. Frederic Thomson has a strong case, for it is obviously difficult to plead economy in questions concerning the preservation of human life. None the less, I feel that we should, when responsible for public money, exercise as rigid an economy as our experience may be held to justify. I agree with Dr. Thomson that it is often impossible to predict the subsequent course of any particular case, and that therefore it is reasonable to play for safety. Still, I think, the evidence of the superiority of the large over the small dose is not so extraordinarily convincing that we need resort to it in every suspicious case, when comparatively small amounts of serum are likely to be effective in the vast majority of cases with which we have to deal.

I must plead guilty to having raised what, I fear, is a somewhat academic question, for, as I suggested in the last lines of my paper, it is most unusual for us to admit to hospital a patient who has received any antitoxin at all. At a recent discussion of the Fever Group of the Society of Medical Officers of Health I found that the experience of the hospital superintendents present was similar to my own, and that the admission of such cases was most exceptional. It would be a great advance if we could convince the practitioner that a case suspicious enough to swab is suspicious enough to treat, and I believe that even the small doses which I recommended would, if given as a routine when the swab is taken, make a remarkable reduction in the death-rate of diphtheria. It is possible, moreover, that such a routine might be more readily adopted if the dose suggested was small and cheap. It doubtless would be less likely to have any effect on the cases which occasionally surprise Dr. Thomson and, I must add, myself, and would be useless in the type described by Dr. B. A. Peters, but it would be of inestimable advantage to a very large number of patients.

Fluctuations in case mortality have occurred from time to time in Edinburgh as in Bristol. I have seen small groups of cases resembling those mentioned by Dr. Peters, usually coming from a particular district for a short space of time. If the type is so general in Bristol I can only congratulate Dr. Peters on a remarkably low death-rate, as I think serum does as little good in such cases as it does in the hæmorrhagic type which, even if treated early, seems invariably to be fatal. It would be interesting if Dr. Peters would tell us the total dosage which he is accustomed to employ for them. Whether they are due to a special strain of bacilli not provided against in ordinary serums, or, as I have sometimes suspected, to a mixed staphylococcal infection, I doubt very much if even the 8000 units advised by Dr. Thomson would do any more good than my own smaller dose.

A great deal seems to depend on whether toxin already combined with tissue can be detached or not.

Dr. William Park seems convinced that it cannot, Prof. Th. Madsen suggests that it can provided very large, 100,000 to 200,000 unit, doses are used. If it cannot, I understand Dr. Madsen to imply that 4000 units will neutralise any free toxin even in a severe case. Dr. Park thinks that more than 25,000 units in a child, or 50,000 in an adult, is quite useless. Even if we decide to be guided by clinical results we get little help and, I submit, not very much encouragement to use large doses. At a meeting reported in last year's Transactions of the American Pediatric Society Dr. E. Place gave interesting statistics of the case mortality of three groups of patients treated at the Boston City Hospital at different periods. All laryngeal and anterior nasal cases are deducted. The 1654 patients of the first group received an average of 1800 units with a case mortality of 8.8 per cent. The 1913 patients of the second group received an average of 15,000 units with a case mortality of 9.4 per cent. In the third group 820 patients, 62 per cent. of whom had intravenous injections, with an average dosage of 30,000 units, showed a case mortality of 7.6 per cent. Even allowing for possible fluctuations in virulence, it is difficult for the supporters of large doses to extract much comfort from these figures, especially as the slight advantage of the third group might be not unreasonably attributed to the intravenous administration. In the discussion which followed Dr. Park stated that, in groups treated with amounts of serum rising from 2000 to 16,000 units, there was practically no difference in the case mortality, though the patients who received the larger doses seemed to make more rapid recoveries. An attempt to dispense with serum altogether produced such results that the experiment was hastily abandoned. On the other hand, Dr. Madsen claims to have lowered his death-rate by the use of colossal doses, such as Dr. J. McCollom introduced many years ago at Boston, but as the case mortality was reduced from 2 to 0.8 per cent. his figures are difficult to compare with those from countries with a higher mortality. It would almost appear that all that we can actually be certain of is that patients who receive serum do very much better than those who do not, and that the earlier the first dose is given the better they do.

My experience of intravenous injection in young children is very much that of Dr. E. W. Goodall, and I reserve this method for very severe cases occurring at an age when a vein is readily accessible. Even then I use it with a certain nervousness, as rigors and collapse, probably the result of protein shock, are not very unusual. I doubt if the method is justifiable except for patients dangerously ill. Dr. Park and, more recently, Dr. Madsen have shown that a fairly rapid concentration of antitoxin can be secured by the intramuscular route, and it is this that I have employed for all cases for the last ten years.

I entirely agree with Dr. Goodall that the fault of the practitioner is waiting for the result of the culture. But some medical men dislike sensitising a patient unnecessarily, and others, influenced by accounts of fatal anaphylactic shock, hesitate to risk an injection until they obtain proof that it is required. As regards the doctor being summoned too late, I fear we can do nothing. Lamentable instances of such delay are only too common, and probably will remain the most important cause of death from diphtheria.

I am, Sir, yours faithfully,

CLAUDE B. KER, M.D.

City Hospital, Edinburgh, April 15th, 1923.

"ENCEPHALITIS LETHARGICA" OR "ECONOMO'S DISEASE."

To the Editor of THE LANCET.

SIR,—Although eponymous terminology is, as a rule, undesirable, there are instances in which it is to be welcomed. Thus, "Graves's disease" is a better term than "exophthalmic goitre," seeing that neither goitre nor exophthalmos is invariably present in it.

Similarly, I would submit, "Economo's disease" is a better designation than "encephalitis lethargica," where neither lethargy nor evidence of encephalitis is essential to the diagnosis; it entails no misapprehension; in fact, it avoids any.

As Prof. A. J. Hall has well said, in his Lumleian lectures, "the name encephalitis lethargica survives chiefly from reasons of sentiment, since it is the one selected by von Economo. By retaining it we pay tribute to his remarkable work; a work rendered even more remarkable by the fact that it was carried out at the height of a great war, under all the difficulties which that involved." I share this sentiment, but think it would be better expressed by giving to the disease the name of its discoverer. When Freiherr von Economo chose the present name, it covered the known facts; now he would probably be the first to admit it no longer does so. His name is so familiar in connexion with the disease that the one immediately recalls the other. I believe the adoption of the term "Economo's disease" would tend to clear the path of further observation.

I am, Sir, yours faithfully,

Exeter, April 17th, 1923.

W. GORDON.

A CASE OF PARKINSONISM WITHOUT INITIAL SYMPTOMS OF ENCEPHALITIS.

To the Editor of THE LANCET.

SIR,—Prof. A. J. Hall has referred in his recent Lumleian lectures to the clinical differences between Parkinsonism and the pre-senile form of paralysis agitans. The following case illustrates some of the points in this connexion. The patient, a married woman of about 35, first came to me as an out-patient at the Miller Hospital in March of this year. She had been treated for some months for indigestion, she always felt tired, took little or no interest in things, and merely wanted to sit about. Her general appearance was characteristic of the Parkinsonian type of disease; she had a mask-like expression, and the typical slow progression and stiff attitude of body with the arms held a little forward, the elbows being slightly flexed. There were none of the movements commonly seen in the ordinary pre-senile type of paralysis agitans, and the clinical picture suggested the Parkinsonian sequelæ of lethargic encephalitis. I went carefully into the previous history expecting to get a story of an attack of so-called influenza, but was unable to elicit an account of any definite febrile period. I saw the patient again at my house together with Prof. Hall. She had not been conscious of any visual disturbances such as might have suggested ophthalmoplegia. The indigestion of which she had complained began apparently about a year ago, a point of some importance, in connexion with the seasonal incidence of the disease. She slept well and could go to sleep easily at any time that she liked, but there was no evidence of her having had any involuntary lethargic periods. On examination the first and most obvious signs were the rigidity of the upper limbs, the general posture, and the mask-like features and extremely fixed expression. The pupils reacted to light and accommodation, but the latter reaction was sluggish and the accompanying convergent movements of the eyes were weak and ill-sustained. There was no true nystagmus, but slight nystagmoid movements and a certain weakness were apparent on extreme lateral movement. There was evident difficulty in fixing objects. The fundus oculi appeared normal on both sides. When the patient was asked to open the hand quickly after making a fist, there was some hesitation and slowness in extension of the fingers. A slight fine tremor was observed when the arms were extended. There was a definite fine tremor of the tongue and slight hemi-atrophy affecting the left side. Some tremor of the lips was also noticed. The knee-jerks were easily obtained and were brisk on both sides. Her general health was good, the indigestion having by this time disappeared. She had had amenorrhœa

for about three months, but the periods had recently come on again; she did not think there had been any question of pregnancy.

Apart from the question of age and the absence of the characteristic pill-rolling movements, the early and comparatively sudden appearance of the mask-like face in this patient was the principal feature which made me think at once of encephalitis lethargica. The interesting features of the case were the insidious onset and the complete absence of evidence of the previous occurrence of any of the sudden symptoms or febrile manifestations which usually characterise the onset of this disease. For this reason this case appears to me to belong to a type which, so far as I am aware, has not hitherto been recorded, namely, that of encephalitis lethargica—"forme fruste"—in which no characteristic symptoms occur in sufficient quantity to attract the attention of the patient or his friends. While in the ordinary types the acute period of the disease may be so short as to be forgotten by patients, a careful review will usually reveal some feature or features which enable one to trace the date of onset with fair accuracy. It is interesting to note that the only previous symptoms mentioned by this particular patient were those of dyspepsia, and it is recognised that gastro-intestinal disturbances may sometimes occur as early symptoms of lethargic encephalitis.—I am, Sir, yours faithfully,

MAURICE DAVIDSON.

Wimpole-street, W., April 20th, 1923.

THE LIFE-HISTORY OF THE TAPEWORM, HYMENOLEPIS NANA.

To the Editor of THE LANCET.

SIR,—In your issue of April 21st my friend, Dr. Wm. Nicoll, corrects a "slightly misleading statement" occurring in a recent issue of the *Tropical Diseases Bulletin* to the effect that Nicoll and Minchin claim to have obtained cysticercoids of *Hymenolepis nana* in fleas. Dr. Nicoll states that no claim was intended, and that there is nothing in the published report (Proc. Zool. Soc., 1911) to suggest such. As the statement referred to occurred in a review of recent contributions to medical helminthology written by me for the *Bulletin*, I may be allowed to say that the claim attributed to Dr. Nicoll and Prof. Minchin rests upon the authors' abstract published by the Zoological Society, November, 1910, which states that one of the cysticercoids found in the fleas "was probably the larva of *Hymenolepis murina*, a species occurring in rats and mice and very similar to, possibly identical with, *H. nana*, a dangerous tapeworm of man." "The chief interest of the discovery lay in the fact that no intermediate host was previously known for this tapeworm." The last sentence (italicised by me) forms the basis of the statement of which Dr. Nicoll complains.—I am, Sir, yours faithfully,

R. T. LEIPER.

London School of Tropical Medicine, Endsleigh-gardens, London, N.W., April 24th, 1923.

HOFMANN'S BACILLUS AND TONSILLITIS.

To the Editor of THE LANCET.

SIR,—In THE LANCET of April 21st Dr. David Smith takes me to task for assuming that Hofmann's bacillus is non-pathogenic. In the work in question the majority of the organisms came from boys without symptoms, and these strains were presumed to be non-pathogenic. However, I should not like to maintain that bacilli with a morphology of the Hofmann type can never cause symptoms. Pathogenicity is an attribute that seems very variable, and under the influence of a suitable environment it is quite conceivable that certain strains of Hofmann-like bacilli are sometimes pathogenic. Many times in sore throats, not resembling diphtheria, I have found Hofmann bacilli as predominant organism, yet in the light of my own experience I have hesitated to ascribe an ætiological significance to this fact.

These bacilli are also frequently associated with true diphtheria bacilli in the throats of both carriers and cases. In the former they may prevent satisfactory demonstration of the toxic diphtheria bacilli, but in actual cases of diphtheria it is very rare to be unable to isolate the toxigenic bacilli from the admixture with atoxic Hofmann bacilli.

In the absence of information as regards the virulence of the bacilli from Dr. Smith's cases; from the fact that some of the patients responded so promptly to specific diphtheria antitoxin; that the clinical condition suggested diphtheria, and yet bacilli which morphologically resembled toxic *B. diphtheria* could not be demonstrated, it seems quite possible that these patients were infected with a toxic diphtheroid of the Hofmann type. The evidence, however, is far from absolute, and even if it were absolute, it does not alter the probability that usually Hofmann's bacillus is harmless. Dr. Smith's interesting series of cases is also strong confirmation of the opinion expressed in my report, that, whatever the bacteriological findings may be, antitoxic serum should be given to any patient whose clinical condition suggests diphtheria.

I am, Sir, yours faithfully,

R.N. College, Greenwich, April 23rd. S. F. DUDLEY.

ANNULAR SHADOWS IN THE RADIOGRAM.

To the Editor of THE LANCET.

SIR,—In the course of some notes on X Ray Examination of the Chest, which appeared in THE LANCET of March 17th (p. 535), we expressed the opinion that radiogram No. 6 showed a small circular cavity at the apex of the left lung. Some of your correspondents take the view that this was not a cavity, but a pleural annular shadow. We therefore take this opportunity of giving more in detail our reasons for thinking this was really a shallow cavity, bounded by a ring of fibrous tissue.

1. There can be no doubt clinically, and all medical men who have had him under observation agree, that his patient has tuberculosis of the lungs, although he now has no sputum or other physical signs.

2. There must, therefore, be a tuberculous focus in the lungs, and the only evidence that exists of this is at the apex of the left lung, where we are of the opinion that a shallow cavity is present.

3. The X ray appearance of this annular shadow is constant, and is present in several radiographs which have been taken at long intervals. It is to be seen on the fluorescent screen, and is as plainly visible from the front as from the back.

We are, Sir, yours faithfully,

BERNARD HUDSON.

Montana, Valais, Suisse, April 16th. PERCY G. SUTTON.

L'AFFAIRE SPAHLINGER.

To the Editor of THE LANCET.

SIR.—I am from Australia commissioned to investigate for the Government of Victoria the Spahlinger treatment for tuberculosis. I thought it best to go straight to Switzerland, and before seeing Mr. Spahlinger I went up the mountains to investigate his treatment in action in a sanatorium. I then came down and spent some days with Mr. Spahlinger at Geneva and his wonderful laboratory and experimental farm with horses, cows, goats, &c. During this time I was constantly examining patients who were being or had been treated along Spahlinger lines—comparing old and present conditions, examining old and recent ray pictures of chests, listening to histories, &c. I then read the reports of a number of cases in journals and in manuscript ready for publication that had received this treatment at the hands of chestmen of repute. I understand I have yet to see cases in England that had undergone this treatment. Any further evidence I feel sure will only confirm me in reporting to my Government that Henry Spahlinger's vaccine and serum treatment in tuberculosis stands by itself, and that the medical pro-

fession should lose no time in taking a definite stand in this matter. But the production of these remedies and prophylaxins is almost at a standstill. The Spahlinger family, once in affluent circumstances, are now almost penniless. They have spent all they had in this self-imposed search for potent anti-tuberculous vaccines and sera. Henry Spahlinger loathes publicity, lives in an atmosphere of patient and cheery altruism, has spurned repeated offers from firms and private individuals to "commercialise" his work—offers that would have resulted long ago in retrieving his family's fortune.

There is still another serious matter. The long strain of work and debt-carrying is beginning to tell on Mr. Spahlinger. There have been for some time unequivocal signs of nerve depletion. Truly there are the makings of a tragedy here.

I am, Sir, yours faithfully,

London, April 17th, 1923. J. F. MACKEDDIE, M.D.

To the Editor of THE LANCET.

SIR.—I first became interested in the work of Mr. Henri Spahlinger, of Geneva, by reading the communication presented to the Paris Academy of Medicine. Unfortunately, I found it impossible at that time to obtain the vaccines and sera, the stock having been exhausted by the experiments carried out in London. In 1918 Dr. Stephani, whom I consider to be one of the highest authorities on tuberculosis in Europe, informed me of the remarkable results which he had obtained with the Spahlinger treatment, invited me to experiment with it, and supplied me with serum. Shortly afterwards I met Mr. Spahlinger, who explained to me the principles of his method and the ideas which had guided him in his research work. The latter coincided in every way with my own ideas.

I used the antitoxins and bacteriolysins in a certain number of cases under experimental conditions which were, however, somewhat unfavourable, since in several instances injections had to be postponed for lack of serum. In spite of this fact, my results were very encouraging. In every case treated, whether of medical or of surgical tuberculosis, the sera exerted a very favourable curative action. With the bacteriolysins I regularly obtained complete drying-up of tuberculous fistulae after four or five injections. My tests brought me to the conclusion that Mr. Spahlinger's researches are extremely interesting. In my opinion they constitute the most rational direction in which search has been made for a specific treatment of tuberculosis. The combination of antitoxic sera and bacteriolytic sera enables one of the most important stumbling-blocks of this specific therapy to be avoided. My results allow me to state that this method is the best means of treatment of medical and surgical tuberculosis, and I shall gladly associate myself with everything that may be done to assist Mr. Spahlinger to popularise the use of his very promising method.

The following is a brief note of a case under my own observation:—

In July, 1918, a small tuberculous nodule appeared at the head of the left epididymis, increasing in four weeks to the size of a haricot bean. Dr. Calot and Prof. Sebileau advised against any surgical intervention. The condition persisted until March, 1919, when the nodule again began to grow, extending along the epididymis until in August, when the head was completely involved, the tumour was three centimetres long and the thickness of the little finger, capping the testicle; there were also several isolated nodules on the latter. In September a small nodule appeared on the right testicle. In October a left hydrocele developed, attaining a capacity of 200 c.cm. At the beginning of November 10 c.cm. of Spahlinger's bacteriolysin No. 5 were given daily by the mouth for three days, and resulted in complete disappearance of the liquid contents of the hydrocele. Ten days afterwards, alternate injections of six 2 c.cm. ampoules of polyvalent bacteriolysins M.1 and M.2 were given, followed after ten days' interval by six similar injections. During the following three weeks' rest generalised troubles appeared—fever, cramp, general fatigue, and loss of appetite—which persisted for a fortnight; at the same time the tumour became progressively smaller, so that after a fortnight the testicle was left entirely smooth, with no trace of tuberculosis, and the same size as the other, from

which the small nodule had also disappeared. The patient's general condition then improved greatly, and a return of the trouble seems improbable; it is now 42 months since the end of treatment.

This case was treated under the observation of Prof. Gosset and Prof. Desmarais, surgeons to the Paris Hospitals and professors in the Faculty of Paris.

I am, Sir, yours faithfully,

CAMILLE SAYOIRE,

Formerly Honorary Director, Dispensaire Antituberculeux de l'Hôpital Beaujon; and Secretary, Commission de la Tuberculose du Ministère de l'Intérieur.

1, Avenue de Parc Monceau, Paris.

THE TREATMENT OF GONORRHOEA WITH A NON-SPECIFIC PROTEIN.

To the Editor of THE LANCET.

SIR,—The gonococcus cannot resist a high temperature, and it has been observed that if an intercurrent febrile disease arises, whilst a patient is suffering from gonorrhoea, or an acute epididymitis complicates the case, the urethral discharge may cease never to return. But attempts to raise the temperature locally by means of electrical instruments have failed as it was found impossible to raise the temperature of the urethra to that of the instrument. Specific vaccines have not proved satisfactory, and the question has arisen whether it is the specific or the non-specific substance in a vaccine which is beneficial. Peptone, serum, and vaccines were at first used as a source of protein, but in 1916 Schmidt and Saxyl reported that protein reactions could be produced by intramuscular injections of sterilised milk. It therefore occurred to me that these injections, which have the power of raising the body-temperature, might have some effect upon the gonococcus.

I have now treated with intramuscular injections of sterilised milk 36 cases (31 males and 5 females) of gonorrhoea, all in the acute or subacute stage. Four of the males were complicated by acute epididymitis and prostatitis. Three were final year medical students who made observations on the effect of treatment. At first 5 c.cm. of sterilised milk were injected into the gluteal muscles. This was followed by a chill, a feeling of general malaise, and a temperature which rose rapidly, reaching a maximum of 102° F. at eight hours, and falling to normal within 24 hours. The general effect varied according to the stamina of the patient. The day following the injection practically no urethral discharge was seen. In the complicated cases all pain, swelling, and discomfort in the testicle and posterior urethra had subsided and only a thin serous discharge was observed at the urethral meatus. On the third day another 5 c.cm. were injected, the reaction following was more severe—probably due to sensitisation—but all symptoms of gonorrhoea disappeared and never returned. In two, however, a recurrence was noted and on investigation a severe infiltration was found in the anterior urethra, due to an old attack of gonorrhoea. After high dilatation a cure was obtained.

It is now my practice to give 10 c.cm. at one sitting, 5 c.cm. into each buttock, and it is very rare that a second injection is required. The dangers attached to this treatment are practically nil; care, however, must be taken that the injections are not intravenous. I met with no anaphylactic phenomena. The mode of action is difficult to explain as the maximum temperature recorded was only 102°, and the effect may be due to the action of non-specific proteins. The results are sufficiently good to stimulate further trial.

I am, Sir, yours faithfully,

Harley-street, W., April 20th, 1923.

M. W. BROWDY.

THE LATE DR. JAMES EVAN JONES.—Dr. Jones, who died at his residence at Ludgershall, Wilts, on April 15th, aged 51, was a student at St. Bartholomew's Hospital, and took the Conjoint qualification in 1895. He was for a time in mining practice in South Wales, moving to Ludgershall on his appointment as surgeon to the contractors for the Tidworth Garrison in 1900. He stayed on to practise in the district and became a great friend of the poor.

Medical News.

UNIVERSITY OF LONDON: *Representation on the Senate*.—A vacancy has arisen in the representation on the Senate of the University of London of graduates in medicine of the University. The two candidates who are standing for election are Robert Arthur Young, M.D., B.Sc. Lond., F.R.C.P., and George Leslie Eastes, M.B., B.Sc., M.R.C.S. L.R.C.P. Both candidates have issued election addresses. Dr. Young, who is supported by the University of London Graduates Association, states that if elected he would endeavour to assist in maintaining the full privileges of Convocation, and would oppose most strenuously any proposal tending to lower the standard or lessen the prestige of the degrees of the University. As a teacher he is in full sympathy with the efforts now being made by the medical faculty of the University to render the curriculum and courses of study in medicine as uniform as possible, so as to simplify the problems of teachers and of students in the medical schools. He feels that it is important that the time devoted to the study of the clinical subjects should in no way be curtailed, but at the same time is fully convinced that the instruction in the preliminary and intermediate subjects should be as thorough and as practical as possible. Dr. Eastes in his election address points out that with the retirement of Dr. T. D. Lister the Senate loses its sole representative of the large element amongst the graduates who are engaged in general or special practice, but are not teachers. His programme includes an endeavour to increase facilities and accommodation for communal life among the students, particularly amongst post-graduate workers; to promote the advancement and more thorough teaching of pathology in the curriculum; and to expedite provision of facilities for post-graduate work. The election will be held on May 2nd.

Course on Medical Hydrology.—A course of lectures for medical practitioners and senior students on Medical Hydrology has been arranged by the University Extension Board of the University of London in co-operation with a Joint Committee of the International Society of Medical Hydrology and the Section of Balneology and Climatology of the Royal Society of Medicine. The lectures will be held at the University of London, South Kensington, and will be supplemented by demonstration, and by clinical instruction at British spas; the course will begin on May 29th and end on June 4th. It is intended for those who are engaged, or propose to engage, in spa practice, for medical officers of hydrotherapeutic institution and sanatoriums, and for others interested in the subject. The University will grant a certificate of attendance to those who have attended the whole course, taking both theoretical and practical work. On May 29th Dr. Leonard Hill, F.R.S., will give the opening lecture on the Physiology of Cold, Heat, and Light. Dr. R. Fortescue Fox will speak on the Qualities and Actions of Medicinal Waters; on the Action and Uses of Baths; and on the Applications of Hydrology to Incipient Disease on May 29th, 30th, and 31st respectively. Dr. Wilfrid Edgecombe will deal with the Treatment of Cardio-vascular Affections by Waters and Baths on May 30th; Dr. Charles W. Buckley will deal with the Hydrological Treatment of Rheumatism, Gout, Infective Arthritis, and Fibrositis on May 30th; and Dr. Rupert Waterhouse will lecture on the Treatment of Nervous Disorders by Waters and Baths on May 31st. Demonstrations of various forms of bath will be given by Mr. H. S. Souttar, Dr. J. Campbell McClure, and Dr. Arthur S. Herbert at the Special Surgical Hospital, Ducane road, Shepherd's Bush, on May 29th, and of the recording katha-thermometer and other methods of controlling open-air treatment by Dr. Leonard Hill, at the National Institute for Medical Research, Hampstead, on May 30th. A study tour to Harrogate will be made, and free hospitality for a limited number will be provided at the spas. All communications with reference to the course should be addressed to Dr. Edgecombe, care of University Extension Department, University of London, Imperial Institute road, South Kensington, London, S.W. 7.

A course of eight lectures on Nutrition will be given by Prof. V. H. Mottram at King's College for Women (6 Campden Hill-road, W.8) on Mondays and Wednesday April 30th, May 2nd, 7th, 9th, 14th, 16th, 23rd and 28th at 4.30 p.m. Attendance at this course is recognised in connexion with the B.Sc. (Honours) degree in physiology.

UNIVERSITY OF GLASGOW.—At the ceremony of graduation on April 17th the Straits Settlements gold medal for thesis for M.D. on a subject in connexion with tropical medicine or tropical hygiene was awarded to Dr. Thomas Mackie. Among special class prizes the Asher Asher gold medal for laryngology and rhinology was awarded to Mr. Murdo Nicolson.

ROYAL INSTITUTION OF GREAT BRITAIN.—The Friday evening discourse on May 4th, at 9 P.M., will be delivered by Prof. Frederick Soddy, F.R.S., on the Origins of the Conception of Isotopes. On May 1st, at 3 P.M., Sir Arthur Keith, F.R.S., will give his fourth lecture on the Machinery of Human Evolution, entitled, Are our Bodies Changing? On May 5th Dr. Leonard Williams will give his second lecture on the Physical and Physiological Foundations of Character. The annual meeting will be held at 5 P.M. on May 1st.

THE LATE MR. G. M. P. MURRAY.—By the sudden death of Mr. George Murray on April 19th the dental profession of Dublin has lost one of its most respected and loved members. Mr. Murray qualified L.R.C.S.I. in 1878, becoming F.R.C.S.I. in 1889, and later a member of the council of the College. He was one of those who built up the Dental Hospital and its Dental School, and for many years he had been honorary secretary of the hospital. His charm of manner and courtesy were the natural expression of an attractive personality and will be much missed.

PRESENTATION TO DR. BYROM BRAMWELL.—The presentation of two portraits of himself to Dr. Byrom Bramwell will take place at the Royal College of Physicians, Edinburgh, on Saturday, May 19th, at 5.30 P.M. The subscriptions obtained have sufficed to provide two portraits, both of which have been painted by Mr. David Alison, R.S.A. At the request of the committee responsible for raising the fund Sir Humphry Rolleston and Sir David Drummond have undertaken to make the presentation. One portrait is to be retained by Dr. Bramwell, and the second is to be presented to the Royal College of Physicians, Edinburgh, and will be received on behalf of the college by Sir Robert Philip.

A CAMPAIGN FOR TWO MILLION SHILLINGS.—The Lord Mayor of Manchester has launched an ambitious scheme in order to obtain two million shillings from the public of Manchester to clear the Manchester hospitals of debt. The Lord Mayor stated that Leeds, Glasgow, and Birmingham had all done more for their hospitals than Manchester for hers. A scheme was taking shape for inducing all workpeople to allot one penny per week from their earnings for the hospitals. If every man and woman employed in the works and warehouses of Manchester would contribute this penny a week £50,000 would be forthcoming annually. A "Flying Week" was launched on April 21st at the local aerodrome, the proceeds to go to the hospital fund. It was announced that £5000 had already been subscribed towards the desired £70,000.

QUEEN MARY'S HOSPITAL.—On April 16th the Countess of Pembroke opened a new wing of Queen Mary's Hospital for the East End, Stratford, E., which will provide accommodation for 40 patients. It has been erected at a cost of some £30,000, of which £10,000 has been given by Mr. Charles Lyle in memory of his wife. On the same date Mr. W. Thorne, M.P., laid the foundation-stone of the West Ham Memorial Hospital, which is to take the form of a new out-patient department of Queen Mary's Hospital equipped with all modern improvements.

COCAINE SUBSTITUTES COMMITTEE.—The Home Office and the Ministry of Health have had under consideration the possibility of the use in medical and surgical practice of substances which might serve the same therapeutic purpose as cocaine, but be free from its deleterious properties. The Minister of Health has decided, after consultation with the Medical Research Council, to appoint a committee with the following terms of reference: "To investigate the comparative value, for the therapeutic purposes for which cocaine is at present used, of various possible substitutes, and the evidence as to risk, if any, of such substitutes becoming drugs of addiction." The committee will consist of Dr. J. Smith Whitaker, a senior medical officer of the Ministry, Chairman; Dr. Norman G. Bennett, dental surgeon, Royal Dental Hospital, London; Dr. R. W. Branthwaite, a commissioner of the Board of Control; Dr. T. Carnwath and Dr. G. F. McCleary, medical officers of the Ministry; Dr. J. H. Chaldecott, senior anaesthetist to St. Mary's Hospital, Paddington, nominated by the Section of Anaesthetics of the Royal Society of Medicine; Dr. H. H. Dale, of the Medical Research Council; Mr. T. B. Layton, surgeon in charge of the Throat and Ear Department of Guy's Hospital, nominated by the Section of Laryngology of the Royal Society of Medicine; Mr. R. Foster Moore, surgeon, Royal London Ophthalmic Hospital, nominated by the Section of Ophthalmology of the Royal Society of Medicine; and Sir William Henry Willcox, nominated by the Home Office. The secretary is Dr. E. W. Adams, a medical officer of the Ministry, to whom all communications relating to the work of the committee should be addressed.

The annual dinner of the Indian Medical Service will be held at the Trocadero Restaurant on Wednesday, June 20th. Tickets and particulars may be obtained from the joint hon. secretary, Colonel J. J. Pratt, I.M.S. (ret'd.), 63, Addison-road, Kensington, London, W. 14.

A SANATORIUM FOR SALFORD.—The Nab Top Tuberculosis Sanatorium at Marple, Cheshire, belonging to the Salford Borough Council, has been formally opened, having been in use for four months. The sanatorium has 100 beds, 95 of which are already occupied. Dr. C. H. Tattersall, lately medical officer of health for the borough, stated at the opening ceremony that the official history of the plan began in 1913, although it was conceived in 1901. Delays from one cause and another arose, and the estimated cost rose from £18,000 to £25,000 in 1914, to £45,000 in 1919, and finally to £88,250 in 1920, when the contractors began work.

FEDERATION OF MEDICAL AND ALLIED SERVICES. A meeting of the Medical Council of the Federation will be held at the offices, Stratford-place, W., on Tuesday, May 1st, when a provisional report will be received from a committee formed to advise regarding death certification and the disposal of the dead. The committee consists of Sir Malcolm Morris, Col. Fremantle, M.P., Mr. H. T. Herring, Dr. Louis Parkes, and Mr. F. W. Davy, with Sir McKenzie Chalmers. Having regard to the "Coroners' Law and Death Certification (Amendment) Bill," recently presented to Parliament by Major Molloy, M.D., M.P., the report will be of topical interest. Mr. Herring will explain its purport to the Council.

THE LATE DR. JERVOIS AARONS.—Dr. Aarons, who died on April 21st after an operation, was educated at the Universities of Sydney and Edinburgh, graduating M.B., C.M. at the latter in 1895, and becoming M.R.C.P. Lond. a few years later. He had held appointments as pathologist and registrar at the Hospital for Women, Soho, and as tutor in midwifery and diseases of women at the Extra-mural School of Medicine, Edinburgh. With Dr. Thomas Wilson he represented the Royal Society of Medicine at the Fifth International Congress of Obstetrics and Gynaecology held at Petrograd in 1910. He was the author of a number of useful little books, including "Golden Rules of Gynaecology," "Gynaecological Therapeutics" (1910), and "Aids to Gynaecology" (1912). Among his colleagues Dr. Aarons was best known for his work on sterility; to this subject he devoted a great deal of attention, and he came to be recognised as one of the foremost authorities upon it. In this branch of medicine he was sincere and enthusiastic without being fanatical, and he was very successful in obtaining results. His gentle and courteous personality undoubtedly went a long way in the winning of the confidence of his patients, and his death will be very widely regretted.

NORFOLK AND NORWICH HOSPITAL.—The annual meeting of the governors of this hospital took place on April 14th. The number of in-patients admitted during the quarter ending March 31st was 780, compared with 758 in the corresponding quarter last year; and the daily average of in-patients was 266, compared with 247 last year. The number of operations had been 699, against 694 last year. In the out-patient department 1145 new cases were treated, and there were 1565 accidents and casualties. In the corresponding period last year these numbers were 900 and 1450 respectively. These figures showed that the work of the hospital was increasing. The chairman of the board of management stated that there was still a debt of £19,000, though the total debt had been reduced by £2000 during the year. He commented on the success of the contributory scheme of maintenance which had realised £17,880, which amount, however, fell short by some £2000 of the total expenses of the patients sent into the hospital under the scheme. The size of the waiting list of patients for admission he connected with the contributory scheme; the local secretary in every parish in the county had made known the work of the hospital, and there was a constant stream of applications for admission. The chairman of the finance committee pointed out that the hospital was erected within the memory of many of those present at a cost of £57,116. The income had increased from £9755 in 1900 to £50,000 in 1922, and investments had increased during the same period from £77,737 to £120,216. The large overdraft at the bank (£19,000) was caused by the two black years 1919 and 1920, when their expenditure exceeded their income by £24,192. It was in receiving and in most cases restoring 8000 wounded men that the Norfolk and Norwich Hospital incurred the heavy liability which seemed destined for years to stay the further progress of the institution. He thought that this would not have been so if Norwich, the only community in Norfolk which had failed to erect a lasting memorial of the war, had admitted the principle that the hospital was far the most fitting object of its beneficence.

Parliamentary Intelligence.

HOUSE OF COMMONS.

WEDNESDAY, APRIL 18TH.

Sale of Useless Disinfectants.

MR. BECKER asked the Minister of Health if his attention had been drawn to the fact that disinfectants totally devoid of bactericidal action were sold to the public; and if he would see that disinfectants so sold and described must comply with a test similar to the one required for the army and navy and other Government departments.—MR. NEVILLE CHAMBERLAIN replied: I have no evidence to show that disinfectants totally devoid of bactericidal action are sold to the public, but I am aware that, judged by certain tests, the disinfectants which are on sale may differ considerably in their bactericidal power. As at present advised, I do not propose to adopt the suggestion in the last part of the question. I understand that advice as to the choice of disinfectants for particular purposes can generally be obtained from the health officers of local authorities.

Panel Practitioners' Remuneration.

MR. TREVELYAN THOMSON asked the Minister of Health whether, in view of the fact that the public generally were primarily affected by any rearrangement of the panel system under the national health insurance scheme, he would appoint a representative committee to inquire into the working of the present system which should include direct representatives of the approved societies and of insured persons; and that he would not sanction any rearrangement of terms before such an inquiry had been made.—MR. NEVILLE CHAMBERLAIN replied: As a result of discussion with the Insurance Consultative Council, it is not now contemplated that any general rearrangement of the insurance medical system will be made. Certain modifications of the terms of services have been recommended by the council, but these will not involve any substantial change in the present system. No case has, in my view, been made out for a separate investigation of the kind suggested by the hon. Member, which would complicate the negotiations and so tend to delay a settlement.

MR. THOMSON: Is the right hon. gentleman aware that the Consultative Council, in the opinion of many approved societies and insured persons, does not adequately represent their point of view?—MR. CHAMBERLAIN: There is no other body that does.

SIR KINGSLEY WOOD asked the Minister of Health whether, in respect of the payment to doctors on the panel list, the Government actuary had advised that at the end of the existing agreements it would be no longer possible for the present payment of 2s. 6d. per patient per annum to be made from the funds of the approved societies; and whether he proposed that any further contributions should be made from State funds in connexion therewith.—MR. CHAMBERLAIN replied: The Government actuary has given no advice on the matter referred to by my hon. friend subsequent to that contained in his report on the Financial Provisions of the National Health Insurance Act, 1922 (Cmd. 1631), a copy of which I am sending to my hon. friend. The answer to the latter part of the question is in the negative.

Vaccination and Small-pox.

MR. SCRYMGEOUR asked the Minister of Health whether his medical advisers had made any report in regard to the higher fatality rate which occurred amongst vaccinated, as compared with unvaccinated, cases of small-pox in England and Wales last year.—MR. NEVILLE CHAMBERLAIN replied: The answer is in the negative. I may, however, say that 24 of the 27 deaths from small-pox in England and Wales last year occurred in the outbreak of virulent small-pox in London and the neighbourhood, and that in this outbreak the fatality rate was 23.7 per cent. in the case of vaccinated persons and 60 per cent. in the case of unvaccinated persons. The age of the youngest vaccinated person who died from small-pox was 43.

Women Insurance Inspectors.

MR. MOSLEY asked the Minister of Health when it was proposed to reorganise the inspectorate of the insurance department in order to carry out Clause 2 of the Resolution of the House of Commons on August 5th, 1921, that women should hold posts in the Civil Service under the same regulations as govern the classification, and, in so far as regards status and authority, other conditions of service for men; and in what respect the duties of the women inspectors of the insurance department differed from those of the men inspectors other than that men and women deal mainly with workers of their own sex; and whether, seeing that the interests of the insured women of this country were adequately safeguarded by the present organisation of the women

inspectorate, he would consider reorganising the male inspectorate on an equally economical basis, and thus saving the salaries of the men divisional inspectors.—MR. NEVILLE CHAMBERLAIN replied: The duties of the men inspectors are to secure compliance with the Insurance Acts and to act within their districts as the local executive officers of the insurance department of the Ministry. The women inspectors are employed in the inspection of trades where women are mainly employed and in inquiries as to the benefits of insured women. The inspectorate is organised with strict regard to the requirements of the work, and it is not proposed to make any change in the organisation at the present time.

The London Ambulance System.

MR. BRIANT asked the Minister of Health if he would nominate a committee to inquire into the adequacy and organisation of the ambulance system for London.—MR. NEVILLE CHAMBERLAIN replied: I will make inquiries with regard to this matter, and if it should appear that any advantage is likely to result, I shall be happy to summon a conference of the various authorities concerned to consider the whole question.

Voluntary Hospitals Grants.

MR. GILBERT asked the Minister of Health whether the whole of the £500,000 Parliamentary grant in aid of the voluntary hospitals had now been distributed; whether the grant would be repeated; and whether the Hospitals Commission, when the present grant had been distributed, would, in accordance with its reference, cease to act.—MR. NEVILLE CHAMBERLAIN replied: I understand that up to the present the Commission have distributed £421,033. The Commission have not yet made any recommendation as to the necessity for any future grant or for the continuance of some central body to act as a link between the local voluntary hospital committee.

Bacteriological Examination of Milk.

SIR JAMES REMNANT asked the Minister of Health whether his attention had been drawn to the representations of the Society of Medical Officers of Health, the British Medical Association, and others relative to the inadequate charges authorised by the Ministry for the bacteriological examination of the various grades of milk under Statutory Rules and Orders, 1922, No. 1332, Dairy England, and Circulars of Ministry of Health, No. 335, August 28th, 1922, and 356, Dec. 12th, 1922, necessitating, as it did, the services of a skilled bacteriologist and the provision of the necessary material; and would he inquire into this.—MR. NEVILLE CHAMBERLAIN replied: I have received representations as to the fee proposed for the examination of samples of milk which are required under the Orders referred to in the question. I am advised that the work in question is of a routine character, and that the cost per sample should not exceed the amount which has been suggested where arrangements are made at a laboratory for dealing with the considerable volume of samples which may be expected to result from the scheme of milk-grading.

Venerical Disease in the Army.

SIR SYDNEY RUSSELL-WELLS asked the Under Secretary of State for War the rates of venerical disease admissions per 1000 per annum in 1921 and 1922 of the British Army of the Rhine, the British Army in Constantinople, and the British Army in the United Kingdom, respectively; whether there was any difference and, if so, what in the methods of medical prophylaxis adopted in the different armies; and whether any steps were taken to prevent soldiers attending civil venerical disease clinics in the United Kingdom in plain clothes.—Lieut.-Colonel GUINNESS replied: The ratios per 1000 are:—

British Army of the Rhine	1921 .. .	212.34
	1922 .. .	213.53
British Army in Constantinople ..	1921 .. .	228.48
	1922 .. .	83.41
United Kingdom	1921 .. .	40.26
	1922 .. .	33.66

The same methods of medical prophylaxis are followed in each of these commands. As regards the last part of the question, there is no prohibition on the attendance of men at such clinics, but they would probably find regular attendance, whether in plain clothes or uniform, difficult in practice.

THURSDAY, APRIL 19TH.

Conditional Pensions.

MR. TOM WILLIAMS asked the Minister of Pensions how many ex-Service men were in receipt of conditional pensions whose injuries were received in the years 1915, 1916, 1917, and 1918, and whose pensions had remained stationary for four years.—Major TRYON replied: The records of my department are not kept in such form as to disclose the particulars asked for, but the great majority of all cases of injury in which pension has been current for four years or more have either received final awards or are about to be considered for final awards.

Special Treatment of Heart Cases.

Mr. BECKER asked the Minister of Pensions if his Ministry proposed to remove ex-soldier and ex-sailor heart cases from special heart treatment hospitals and clinics and place these men under panel practitioners who were not heart specialists.—Major TRYON replied: The answer is in the negative. So long as the condition requires institutional treatment it will be provided. Treatment under the man's panel doctor is only recommended when the case is within the competence of the average medical practitioner.

Medical Classification of School-children.

Mr. CECIL WILSON asked the President of the Board of Education the number of children already examined by the medical staffs and certified as mentally defective for whom no accommodation was available; and the number of children reported as mentally defective who still required to be specially examined by school medical officers.—Lord EUSTACE PERCY (Parliamentary Secretary to the Board of Education) replied: My latest statistical information on this subject is contained in Appendix F of the Chief Medical Officer's Report for 1920. It would appear that in 293 areas for which data have been tabulated, there were, approximately, 28,000 children reported as mentally defective in the category of "feeble-minded." This includes children under the Local Control Authority. The total accommodation provided in certified special schools for educable mentally defective children is over 16,000. With regard to the last part of the question, the only definite information I have is that furnished by the medical officers themselves.

Statutory Salary for Health Visitors.

Mr. ALBERT BENNETT asked the Minister of Health whether he would consider the whole question of appointing or suggesting a statutory salary for health visitors so as to avoid the under payment which was too frequent at the present moment.—Mr. NEVILLE CHAMBERLAIN replied: The general question of the salaries of health visitors is receiving my consideration.

Workshops for Blind Persons.

Mr. GROVES asked the Minister of Health the number of workshops for the blind which have been opened in connexion with the operation of the Blind Persons Act, 1920; and whether the utilisation of the charitable institutions had given the help that his department anticipated.—Mr. NEVILLE CHAMBERLAIN replied: Since the passing of the Blind Persons Act, 1920, four new workshops have been opened and considerable extensions have been made to six existing workshops. The answer to the latter part of the question is in the affirmative.

FRIDAY, APRIL 20TH.

Prohibition of Liquor Traffic.

Mr. SCRYMGEOUR moved the second reading of the Liquor Traffic Prohibition Bill. He said that if drink was an enemy they had no right to compromise with it. Those who were engaged in the drink trade paid the penalty. They died off more rapidly than people engaged in other business, and they had to pay a higher premium for life insurance.

Dr. SALTER, in seconding the motion for the second reading of the Bill, said he doubted if the methods of the machinery of the Bill were good. The real case for prohibition was scientific and sociological. The House had taken strong action against dangerous drugs because they tended to anti-social actions. The position in regard to the drug alcohol was exactly the same. The first effect of alcohol on the system was to diminish the higher power of self-control. He asked how many Members of the House could say that they had got a clean bill of ancestral mental health, how many among the general population could say that they had not got lurking in their system some taint inherited from a progenitor who was eccentric, unstable, crotchety? He knew distinguished men in his own profession who showed all through their lives self-control, complete mental stability, and when they were 50 or 55 succumbed to the alcoholic habit. Undoubtedly there were a large number of persons who were as susceptible to alcohol as the majority of people were to morphia and cocaine—that was, they could not help becoming slaves to the drug once they started taking it.

Sir A. HOLBROOK moved the rejection of the Bill. He said that prohibition in America had produced more corruption than any law introduced into that country. There was more drunkenness now in America than there had ever been. He claimed to be a temperance reformer, but the way to produce temperance was to see that the liquor shops were not the confined, ill-ventilated places they were to-day, but to get them wide open places on the continental café system. If they destroyed the drink traffic they would have to find some other means of taxation to balance the loss. He was in favour of a restriction on the sale of spirits, but he was opposed to a restriction on the sale of beer. His main objection to the Bill was that it infringed the British idea of freedom.

Viscount CURZON, in seconding the motion for rejection, said that legislation which would lead to evasion and manufacture criminals as this Bill would do was bad.

Dr. CHAPPLE said that total abstainers had an advantage in life expectancy over moderate drinkers of 22.3 per cent. He was against prohibition by Act of Parliament, but not against it by local option.

On a division the Bill was rejected by 236 votes to 14—majority against, 222.

Education Medical Service.

Sir JOHN LEIGH asked the President of the Board of Education whether the promised close co-operation between his department and the Ministry of Health was now effective; whether the school medical officers were working with medical officers of health without any serious friction; and how many medical staff he was retaining in addition to those at the Health Ministry.—Lord EUSTACE PERCY replied: The answer to the first part of the question is in the affirmative, and also the answer to the second, so far as I am aware. The number of medical officers engaged exclusively at the Board of Education is seven.

MONDAY, APRIL 23RD.

Medical Herbalists Bill.

Lieut.-Commander KENWORTHY presented a Bill to provide for the registration of medical herbalists, which was read a first time.

Membership of the Board of Control.

Mr. AMMON asked the Minister of Health whether he would consider the advisability of appointing to the Board of Control on the Mental Nursing Service a representative from the joint conciliation committee of the Mental Asylum Workers' Union and the Mental Hospitals' Association, which represented a great majority of the asylums authorities.—Mr. NEVILLE CHAMBERLAIN replied: I assume that the hon. Member is referring to the committee which was appointed by the Board of Control in March, 1922, to report upon the nursing service in county and borough mental hospitals. This committee hope to report shortly, and the Board of Control do not consider that at this stage it would be desirable to add to its membership. The joint conciliation committee have already been informed that the nursing committee would be willing to consider a statement of any views which the Mental Hospitals' Association and the National Asylum Workers' Union would desire to put before them.

Functions of the Board of Control.

Mr. AMMON asked the Minister of Health whether, in view of the fact that the Board of Control had no legislative power and cannot enforce their recommendations on the visiting committees, he would consider the advisability of abolishing the Board of Control and transferring its present functions to the Ministry of Health.—Mr. NEVILLE CHAMBERLAIN replied: The powers of the Board of Control and their relation to local authorities and to Parliament were fully considered when the Board was established, and I do not consider that there are adequate grounds for initiating measures to alter the present arrangements.

Practitioners and Panel Service.

Sir KINGSLEY WOOD asked the Minister of Health whether his attention had been drawn to a communication recently issued by the British Medical Association to doctors on the panel lists, entitled Organisation of Insurance Practitioners in consideration of, and in the event of, a refusal of the terms offered by the Government for National Health Insurance work, which contemplated a refusal in certain contingencies to carry on the panel service; and what action he proposed to take in such a contingency.—Mr. NEVILLE CHAMBERLAIN replied: The communication to which the hon. Member refers is understood to be a confidential circular issued only to insurance practitioners, and I have no official knowledge of it. Negotiations with representatives of insurance practitioners with a view to the revision of their terms of service have now begun, and the prospects of a successful issue would not be enhanced by any statement at this stage as to the steps which the Government might find it necessary to take in a contingency which I have every reason to hope will not arise.

Sir KINGSLEY WOOD asked the Minister of Health whether he was aware that the Government actuary advised in 1922 that at the end of the existing agreements with doctors on the panel it would be no longer possible for the present payment of 2s. 6d. per patient per annum to be continued to be paid from approved societies' funds; and whether he had given any further report or advice since that date.—Mr. NEVILLE CHAMBERLAIN replied: No, Sir. In reporting on the financial provisions of the National Health Insurance Bill of 1922, the Government actuary did not give the advice which the question suggests, but merely indicated that his opinion that the charge proposed by the Bill could be safely borne applied strictly to the proposals of that measure and should not be held to imply that larger or more pro-

tracted additional charges could be borne by societies. No further report or advice has since been received from him on the subject.

Compensation for Faulty Vaccination.

Mr. ROBERT YOUNG asked the Minister of Health whether, seeing that the operation of vaccination was in many cases enforced, he would see that where untoward results ensued compensation for loss of health and employment wages would be paid, seeing that vaccination was *prima facie* in the interests of the community.—Mr. NEVILLE CHAMBERLAIN replied: The Vaccination Acts do not provide for the compulsory vaccination of adults, and I am advised that there is no statutory authority for the payment of compensation out of the rates in the circumstances to which the hon. Member refers.

TUESDAY, APRIL 24TH.

Ex-Service Men and Deafness.

Captain BERKELEY asked the Minister of Pensions whether his attention had been drawn to the serious difficulties of ex-Service men deafened by the war; whether he was aware that this disability imposed a handicap upon a man seeking employment fully as great as that suffered by a man who had lost his sight; and whether he could see his way to make a special effort on behalf of these men, similar to that already made on behalf of blinded soldiers, both with regard to training for and the obtaining of employment.—Captain CRAIG replied: My right hon. friend is not prepared to admit that the rate of 70 per cent. given under the Royal Warrant for total deafness compares unfavourably with the 100 per cent. rate given for total blindness. The general question of training and employment for ex-Service men is one for the Minister of Labour, but I understand that men who were prevented by deafness due to war service from resuming their pre-war occupation, and who applied to that department, have been trained in some other suitable form of occupation.

Medical Diary.

SOCIETIES.

THE ROYAL SOCIETY, Burlington House, W.

THURSDAY, May 3rd, 4.30 P.M.—*Papers to be read*:—F. A. E. Crew: Studies in Intersexuality. I. A Peculiar Type of Developmental Intersexuality in the Male of the Domesticated Mammals. (Communicated by Prof. R. C. Punnett.) *Papers to be read in title only*:—E. J. Morgan and J. H. Quastel: The Reduction of Methylene Blue by Iron Compounds. (Communicated by Prof. F. G. Hopkins.) C. Balls, D.Sc.: The Determiners of Cellulose Structure as seen in the Cell Walls of Cotton Hairs. (Communicated by Dr. F. F. Blackman.) I. de B. Daly: The Influence of Mechanical Conditions of the Circulation of the Electro-cardiogram. (Communicated by Prof. E. H. Starling.)

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Tuesday, May 1st.

ORTHOPÆDICS: at 5.30 P.M. (Cases at 5 P.M.)

Annual General Meeting:

Election of Officers and Council for 1923-24.

Cases: Mr. P. Bernard Roth: Case of Osteitis Deformans.

Other cases will be shown.

Wednesday, May 2nd.

SURGERY: at 5.30 P.M.

Annual General Meeting:

Election of Officers and Council for 1923-24.

Paper:

Mr. P. Lockhart-Mummery: The Technique of Resection and Anastomosis of the Colon for Tumour.

Thursday, May 3rd.

OBSTETRICS AND GYNÆCOLOGY: at 8 P.M.

Annual General Meeting:

Election of Officers and Council for 1923-24.

Specimens:

Mr. L. C. Rivett: (1) Calcified Tumour of the Recto-vaginal Septum. (2) A Ruptured Hematoma of the Ovary with Extensive Intra-peritoneal Hemorrhage.

Papers:

Mr. L. P. Pugh: Investigation into Ovarian Disease in Cows.

Dr. Archibald Donald: The Clinical Aspects of Adenomyomata of the Female Pelvic Organs.

Friday, May 4th.

LARYNGOLOGY: at 4.45 P.M. (Cases at 4 P.M.)

Annual General Meeting:

Election of Officers and Council for 1923-24.

Cases and Specimens will be shown by Sir StClair Thomson, Sir James Dundas-Grant, Dr. H. Smurthwaite, Sir William Milligan, and others.

Saturday, May 5th.

THERAPEUTICS AND PHARMACOLOGY.

Provincial Meeting at Cambridge in the Pharmacology Laboratory, Downing-street.

Will Members able to attend send in their names not later than April 27th to the Hon. Secretary, Dr. J. H. Burn, National Institute for Medical Research, Hampstead, N.W. 3.

Saturday, May 5th, and Sunday, May 6th.

BALNEOLOGY AND CLIMATOLOGY.

Provincial Meeting at Oxford.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, London, W.C.

MONDAY, April 30th.—5 P.M., Prof. Shattock: Spina Bifida, &c.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith-road, W.

MONDAY, April 30th.—10 A.M., Mr. MacDonald: Genito-Urinary Operations. 12 noon, Mr. Simmonds: Applied Anatomy. 3 P.M., Mr. Simson: Diseases of Women.

TUESDAY.—10 A.M., Mr. Steadman: Dental Department. 12 noon, Dr. Burrell: Chest Cases. Dr. Pritchard: Visit to Medical Wards.

WEDNESDAY.—10 A.M., Mr. Banks-Davis: Throat, Nose, and Ear. 11 A.M., Mr. Simson: Gynæcological Demonstration. 2 P.M., Mr. Gibb: Eye Department.

THURSDAY.—12 noon, Mr. Simmonds: Demonstration of Fractures. 2 P.M., Mr. MacDonald: Genito-Urinary Department. 3 P.M., Dr. Scott Pinchin: Medical Out-patients.

FRIDAY.—10 A.M., Dr. Drummond Robinson: Gynæcological Operations. 12 noon, Dr. Flett: Radiology. 3 P.M., Mr. Sinclair: Surgical Out-patients.

SATURDAY.—9.30 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Saunders: Medical Diseases of Children. 10 A.M., Mr. Banks-Davis: Operations on Nose, Throat, and Ear.

Daily, 10 A.M. to 6 P.M., Saturdays 10 A.M. to 1 P.M., In-patients, Out-patients, Operations, Special Departments.

NORTH-EAST LONDON CLINICAL SOCIETY, Prince of Wales's General Hospital, Tottenham.

WEDNESDAY, May 2nd.—8 P.M., Dr. Browning Alexander: Medical Aspects of Enlarged Thyroids.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

Demonstration of Clinical Cases at 3.30 P.M.

MONDAY, April 30th.—Dr. J. Browning Alexander: Medical.

TUESDAY.—Mr. Howell Evans: Surgical. (3 P.M.)

WEDNESDAY.—Mr. Norman B. B. Fleming: Eye Cases.

THURSDAY.—Mr. H. W. Carson: Surgical.

FRIDAY.—Dr. C. E. Sundell: Diseases of Children.

LONDON HOSPITAL MEDICAL COLLEGE, Mile End, E.

TUESDAY, May 1st.—5.15 P.M., Dr. Millais Culpin: Instinct and Emotion.

FRIDAY.—5.15 P.M.: Dissociation.

LONDON SCHOOL OF MEDICINE FOR WOMEN, 8, Hunter-street, W.

TUESDAY, May 1st.—5 P.M., Prof. A. L. McIlroy: Maintenance of Physiological Conditions during Pregnancy.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, May 3rd.—4 P.M., Dr. Donald Paterson: Intestinal Disturbances in Infancy.

LONDON LOCK HOSPITAL, 91, Dean-street, W.1.

MONDAY, April 30th.—5 P.M., Mr. C. Gibbs: Anterior and Posterior Urethritis.

INSTITUTE OF PATHOLOGY AND RESEARCH, St. Mary's Hospital, Paddington, W.

THURSDAY, May 3rd.—4.30 P.M., Prof. W. Bulloch: Spallanzani's Researches on Respiration.

INFANTS HOSPITAL, Vincent-square, S.W.1.

MONDAY, April 30th.—6 P.M., Dr. Eric Pritchard: General Principles of Feeding and Dietetics as Applied in Breast Feeding.

THURSDAY.—6 P.M., Artificial Feeding.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE LECTURES.

TUESDAY, May 1st.—4.15 P.M., Dr. T. H. Oliver: Malignant Endocarditis.

UNIVERSITY OF BRISTOL POST-GRADUATE DEMONSTRATIONS (in the Medical Theatre).

THURSDAY, May 3rd.—3.30 P.M., Dr. N. Neild: Endocrinology.

FRIDAY (at Dorchester).—Prof. Walker Hall: Normal and Acquired Resistance to Disease.

Appointments.

HIGGINS, T. S., M.D. Lond., D.P.H., has been appointed Medical Officer of Health and Public Health Lecturer at Capetown. WILLIAMSON, O. K., M.D. Camb., F.R.C.P. Lond., Consulting Physician to City of London Hospital for Diseases of the Heart and Lungs.

Paddington Green Children's Hospital: OLIVER, T. C., M.R.C.S., L.R.C.P. Lond., House Physician; DICK, B. M., M.B., Ch.B. Edin., House Surgeon.

Vacancies.

For further information refer to the advertisement columns.

Bedford County Hospital.—H.S. £175.
 Birkenhead Borough Hospital.—Jun. H.S. £150.
 Brighton County Borough Sanatorium.—R.M.O. £300.
 Cambridge, Addenbrooke's Hospital.—H.S. £130.
 Chelsea Hospital for Women, Arthur-street, S.W.—S.
 City of London Hospital for Diseases of the Chest, Victoria Park, E.—H.P. £125.
 Croydon, County Borough of.—Asst. M.O. £700.
 Elizabeth Garrett Anderson Hospital, Euston-road.—Asst. Phys.
 Georgetown Public Hospital, British Guiana.—Radiographer. £350.
 Gloucestershire Royal Infirmary.—Hon. Radiologist.
 Hospital for Epilepsy and Paralysis, Maida Vale, W.—Med. Reg. £100.
 Hospital for Sick Children, Great Ormond-street, W.C.—Clin. Asst. M.O. in Venereal Dept. £1 ls. per visit.
 Hull Royal Infirmary.—Hon. P. and Hon. S.
 Leicester, North Evington Poor-law Infirmary.—R.M.O. £300.
 Liverpool, Royal Southern Hospital.—Hon. Asst. P.
 Maidstone, Kent County Ophthalmic Hospital.—H.S. £250.
 Manchester, Ancoats Hospital.—Surg. Reg. £100.
 Manchester Ear Hospital, All Saints.—Pathologist. £25.
 Manchester Royal Infirmary.—Radiological Registrar. £250.
 Middleser Hospital, W.—Radium Officer. £300.
 Mount Vernon Hospital for Tuberculosis, &c.—Surg. Laryngologist.
 Norwich, Norfolk and Norwich Hospital.—H.S. £150.
 Nottingham City Asylum.—Jun. A.M.O. £100.
 Votts County Council.—Female Asst. Maternity and Child Welfare M.O. £500.
 Prison Medical Service.—M.O. £300.
 Redhill, Surrey, Royal Earlswood Institution for Mental Defectives.—Jun. Asst. M.O. £250.
 Richmond Royal Hospital.—Asst. H.S. £100.
 Rotherham Hospital.—Sen. H.S. £250.
 Royal Alexandra Hospital for Sick Children.—H.S. £120.
 Royal Chest Hospital, City-road, E.C.—P.
 Royal Ear Hospital, Dean-street, Soho.—Hon. H.S. Hon. Anesth.
 Royal Northern Hospital, Holloway, N.—H.S.'s. £100.
 St. George's Hospital, S.W.—P. Also Asst. P.
 St. Helens Hospital, Lancashire.—R.M.O. £250.
 Salford Union Infirmary, Hope, Pendleton, near Manchester.—First Asst. Res. M.O. £100.
 Scarborough Union, &c.—Dist. M.O., &c. £90.
 Sheffield Royal Hospital.—Asst. Cas. O. £150.
 South Mimms, Barnet, Clare Hall Sanatorium.—Asst. M.O. £350.
 Throat Hospital, Golden-square, W.—Hon. Registrars. Also Hon. Asst. S's.
 University College Hospital, Gower-street, W.C.—Holiday Surg. Reg. £2 2s. weekly. Asst. Radiologist. £300. Res. M.O. £150.
 West London Hospital, Hammersmith-road, W.—Hon. Med. Radiologist.
 The Chief Inspector of Factories, Home Office, Whitehall, S.W., announces the following vacant appointments: Abercraive (Brecon); Sherburn (York E. R.).

Notes, Comments, and Abstracts.

HUTCHINSON THE NATURALIST; SUTTON THE PHILOSOPHER; HUGHLINGS JACKSON THE SEER.¹

By R. HINGSTON FOX, M.D. BRUX., M.R.C.P. LOND.

THE Hunterian Society was founded in 1819, 26 years after the death of John Hunter, by Sir William Blizard, who was then 75 years of age, and others. Blizard was president of the Society for three years, and was otherwise remarkable for having remained on the active staff of the London Hospital as a surgeon for 50 years until he retired at the age of 90. The early years of the Society were the era of Hunter's pupils, from whom nearly all the early presidents of the Royal College of Surgeons were drawn. William Clift, the pupil of Hunter and conservator of the museum, was one of the Fellows of the Society. Events moved rapidly in the medical world in the Society's early years.

The Stethoscope.—Anæsthetics.—Antiseptics.

The stethoscope, first used by Laennec in 1819, gradually gained adherents, although it was many years before the art and science of auscultation were built up in the face of a good deal of conservative prejudice. Thus Benjamin Robinson, a physician to the London Hospital in 1823, stated that the stethoscope "did not convey much." The early instruments were very cumbersome and heavy (one such was exhibited). With the increasing knowledge of auscultation came a knowledge of phthisis and pneumonia and a great advance in thoracic surgery. Empyemata were diagnosed and opened; Dr. Thomas Davies, an early president, had known recovery to follow the liberating of eight pints of matter from the chest. The slow progress made by this instrument could be gauged by the fact that the Hunterian orator of 1832 was led to incite his hearers to the use of the stethoscope.

In contrast to this slow progress *anæsthesia* made rapid bounds into favour. Ether was first used in America by Morton, the dentist, and Warren, the surgeon, in 1816; Sir James Simpson, of Edinburgh, introduced chloroform within a year. Liston performed an amputation through the thigh under ether anæsthesia at University College Hospital in 1817, and within 18 months Curling stated that thousands of operations had been performed with the aid of anæsthetics. The minutes of the Society at the period showed, however, that there was a spirit of criticism even of this advance in medicine; the occurrence of post-anæsthetic vomiting came in for a good deal of unfavourable comment. While the benefits to surgery of anæsthesia were now very obvious, it must not be thought that pre-anæsthetic surgery was unskillful; on the contrary, surgery had attained a high level without this aid.

Lister first employed carbolic acid in 1865, but did not publish his first work on *antiseptics* until two years later. The dangers of sepsis at this period might be estimated from the fact that Maunder had on one occasion advocated the tying of the femoral artery in a case of compound fracture involving the knee-joint "to prevent the occurrence of acute traumatic arthritis." This treatment was adopted, and it was stated, with success. As in the case of the stethoscope, there was a good deal of opposition to the antiseptic regime, and often with good cause, for fatal carbolic gangrene was very common before the dangers of this antiseptic were fully understood. Couper commented favourably on carbolic acid, but Bryant, of Guy's Hospital, writing on "traumatic fever and pyæmia," said that antiseptics did not prevent these disorders. The Hunterian orator of 1876 spoke sarcastically of the "fungoid origin of disease" and of the "disgusting odour of carbolic acid." It was not until 1880 that carbolic acid was tested and proved and the antiseptic regime generally came into vogue.

Distinguished Fellows of the Society in its Earlier Years.

These included Sir Richard Owen, son-in-law of Clift, most famed as a zoologist. Richard Bright, the president in 1815, was an unsurpassed observer of disease. One of the governors of the London Hospital had resented having Bright as his neighbour at the hospital dinner on the ground that Bright was the "inventor of a disease." Dr. Robert Barnes, the obstetrician, was another president; he was distinguished for his fine command of English. Sir Andrew Clark, a dramatic teacher, acquired one of the largest practices ever known, and reaped a large harvest. It was stated that he once received a fee of 5000 gns. for a journey as a consultant to the South of France; being a generous man he gave the greater part of this fee to hospitals.

¹ Abridged from an address delivered at the annual general meeting of the Hunterian Society on April 23rd, 1923.

Births, Marriages, and Deaths.

BIRTHS.

CAREY.—On April 16th, at Ravenslea, Brislington, the wife of R. S. Carey, M.R.C.S., L.R.C.P., of a daughter.
 LAPAGE.—On April 17th, at 194, Wilmslow-road, Withington, Manchester, the wife of C. P. Lapage, M.D., F.R.C.P., of a son.
 SOUPER.—On April 17th, at Victoria-street, Aberdeen, the wife of Dr. H. Ross Souper, of a son.

MARRIAGES.

GRANGE—NUTKINS.—On April 19th, at St. John's Church, Putney, Frank Arthur Grange, M.B., B.S., M.C., to Yvonne Vera, daughter of the late William George Nutkins and granddaughter of Alfred Saunders, of Putney.
 HILLMAN—MILLER.—On April 23rd, at Christ Church, Lancaster-gate, Oscar Stanley Hillman, M.B., F.R.C.S., to Ethel Florence Miller, daughter of Mrs. Archie Cameron, of Calcutta.
 KINGDON—LEE.—On April 18th, at St. Pancras Church, W.C., Alfred Thomas Lock Kingdon, M.R.C.S., L.R.C.P., to Kathleen Adelia, only daughter of Mr. and Mrs. Edward Lee, of Digboi, Assam.

DEATHS.

ARONS.—On April 20th, at a nursing home, London, Dr. Jervois Aarons, of Harley-street, W.
 ONES.—On April 15th, at a nursing home, Salisbury, James Evan Jones, M.R.C.S., L.R.C.P., of Ludgershall, Wilts. (Interred New Quay, Cardiganshire.)
 POTTER.—On April 16th, at a nursing home in London, James C. Potter, M.D., F.R.C.S. Edin., aged 54 years.

¹ A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Hutchinson the Naturalist.

Jonathan Hutchinson, surgeon to the London Hospital from 1859 to 1883, was a man of varied interests and remarkable depth of vision. It was said of him by a friend that "he was the best general practitioner I ever knew." He was best known for his work on syphilis, which he first described in its varied stages and compared to a specific fever, and especially congenital syphilis. Hutchinson's "triad" of congenital syphilitic lesions, the teeth, corneal affections, and labyrinthine disease, was still referred to. But this was not a sufficient field for his energy. Skin diseases were all known and described by him so well that to-day there was little to add to his work. He also carried out much careful work on the local origin of cancer and on arthritis and yet found time to carry on a large practice. He was an admirable teacher, though without the large manner of Sir A. Clark, and left in the minds of his pupils a clear impression of the main essentials of his subject. In person he was tall and of athletic build with jet black hair; he was a good horseman. His wide interests included zoology, botany, history, and social science; he took a keen interest in museums and founded several. At a dinner given to him at the age of 70 he ascribed much of his success to the fact that he was a member of the Society of Friends, and it might well be that his association with that society was instrumental in forming his simplicity of character and in developing his talent for hard work. He joined many societies in his youth and spoke at their meetings almost daily. Hutchinson was, above all things, an observer of nature, and in this he was a close follower of John Hunter; disease he regarded as nature gone astray.

Sutton the Philosopher.

Henry Gawen Sutton, physician to the London Hospital from 1867 to 1891, was a thick-set man below middle height, with a large shaggy head; he was most remarkable for his smile which, while not cynical, seemed pitying and was accompanied by a penetrating glance. He was oracular in his speech and wrote very little, but by sheer hard work he acquired a profound knowledge of morbid anatomy. He never appeared to be in a hurry and spent many hours daily in the wards and even more in the post-mortem room. He thought much on "ease and disease," and was fond of speculating on "Nature's way." His philosophic habit of mind was well attuned to the long walks he used to take in the country, and he once described how he felt the rhythm of a brook impress itself upon his own life. His greatest weakness was in his belief in the value of alcohol both for his patients and himself, and his consumption of port could hardly have benefited his gout. He died before reaching the age of 60, leaving to posterity little published work other than his paper with Sir William Gull on arterio-sclerosis. Yet he did much to advance morbid anatomy and had a profound influence on a few pupils.

Hughlings Jackson the Seer.

John Hughlings Jackson, the founder of modern neurology, was "discovered" by Hutchinson, who persuaded him not to abandon medicine. His first published work on nervous disorders was full of wild speculations based on Owen's theory of vertical clefts, but later he became a close adherent of scientific truth based on observation. When the functions of the brain were only beginning to be understood Jackson carried the idea of "centres" forward step by step from his observations on disease; he distinguished between "discharging" and "destroying" lesions, and traced the descent of "representation and control" from level to level in the brain and spinal cord. With the ophthalmoscope he appeared to see into the brain. With reference to his researches on aphasia, it was interesting that neurologists were now coming back to his original views. His written communications were brief and difficult to understand as they were "peppered with explanatory phrases and footnotes," so that for a time he got little hearing. In 1873, however, the experimental work of Ferrier and others abundantly proved the truth of Jackson's theories. A shy, retiring, and contemplative man with a weak voice, he was helped perhaps as much by his sense of humour as by his power of hard work.

INFANT WEIGHING MACHINES ON HIRE.

THE cost of an infant weighing machine sufficiently accurate for use in test feeds is prohibitive for many households, with the result that breast-feeding may be discontinued in cases where it might well be supplemented. It is not generally known that suitable infant weighing machines, costing £6 15s. to buy and said to be sensitive to 2 drachms, may be hired from Mr. C. Pollard, of 130, York-road, London, N. 1, on the following terms: Deposit of £3 on or before delivery in London, 10s. for hire for the first month, and 5s. for each month or part of a month after. Delivery and collection is free in London except in cases where a scale is wanted immediately, a charge of 2s. 6d. is made for sending a machine by special messenger. If the scales are required outside London the hirer pays carriage both ways.

THE MILLIWATT ELECTRIC HEATING PAD.

WE have received from Mr. R. T. Durran, of 76, Victoria-street, London, S.W. 1, an electric heating pad which possesses certain advantages of convenience and economy, and which can be used in many cases where heat is required for either therapeutic purposes or personal comfort. The electrical element consists of fine resistance wires enclosed in asbestos, this again being encased in linen, over which is a flannel material and the whole fits into a white washable slip. The heating element, which can be adapted to various voltages, is connected by a flexible cord to a lamp-socket or wall-contact of the electric light main. A rotary switch attached to the connecting cord allows the heat to be adjusted according to requirements and any danger of over-heating is guarded against by a "cut out," which switches the current off if the temperature rises above 185° F., while the current is automatically switched on again as soon as the pad begins to cool. In addition to the Roman figures on the switch indicating "current off," "mild heat," "medium heat," and "greatest heat," there are raised bosses which enable adjustment to be made in the dark by the sense of touch alone. The pad is flexible and nearly as soft as an ordinary cushion. The apparatus is admirably adapted for the application of continuous heat to any part of the body where it is required.

THE UNIVERSITIES' YEAR BOOK FOR 1923.

WE have received from Messrs. G. Bell and Sons a copy of the Year Book of the Universities of the Empire, 1923, edited by Mr. W. H. Dawson, and published for the Universities Bureau of the British Empire (692 pages; price 7s. 6d.). Within the compass of a handy and attractive volume Mr. Dawson has condensed, with conspicuous success, the essential information contained in the calendars of the 66 universities of the British Empire. These calendars, he tells us, occupy several yards of shelf in the library of the Universities Bureau. Chapters introductory to the several sections give such information regarding their history, regulations, and practice as the universities share in common. Each section comprises three parts (1) a directory of the officers and members of the teaching staff; (2) general information of equipment, degrees, scholarships, and fees; and (3) events of outstanding interest during the past academic year. Appendices contain the regulations and conditions governing admission to various professions and careers. The section dealing with medical and dental qualifications and studies occupies 16 pages and gives the several medical qualifications with a useful précis of the conditions of registration. The Royal Colleges of England, Scotland, and Ireland also receive notice. An interesting chapter in the appendix gives an account of the conference of Swiss and British Universities held at Basle last August when the mutual recognition of University examinations and degrees was discussed and considerable progress made towards reciprocity. Not the least valuable part of the Year Book is an index of 46 pages which must contain nearly 10,000 names to which reference is made in the text.

PUBLIC HEALTH IN JAMAICA AND BAHAMAS.

Jamaica.—The estimated population at the close of 1922 was 871,114. The birth-rate for the year was 34.9 per 1000 and the death-rate 28.3 per 1000. In Kingston, the capital, the principal causes of death were: Diarrhoea and enteritis, 14.8; atrophy, icterus, and scleroma of the new born, 8.5; phthisis, 8.2; enteric fever, 7.1; pneumonia, 6.8; heart disease, 4.6; chronic Bright's disease, 3.7; cerebral hæmorrhage, apoplexy, 3.3. Matters in connexion with the health and sanitation of the island have been receiving for some time past the earnest attention of the Government and active steps were taken during 1921 for dealing with such matters. The Rockefeller Foundation continued the operations in Jamaica in connexion with the treatment of hookworm, and the United Fruit Company carried on the system for medical attendance on their employees. Both these organisations have materially contributed to improve general health conditions in the island. It is in contemplation to appoint a senior sanitary medical officer and to obtain for the colony a general sanitary service. The epidemic of alastrim, or Kafir milk-pox, which occurred during 1920, still existed in 1921, but to a milder extent.

Bahamas.—The estimated population on Jan. 1st, 1922, was 56,151. The birth-rate for 1921 was 38.2 per 1000, and the death-rate 20.5 per 1000. The public health was no so good as in the previous year. Typhoid was more prevalent than usual, and there was a very persistent and prolonged epidemic of dengue fever, which appears also to have been very fairly common all over Florida. The rainfall for the year was 46.83 inches. The General Hospital (originally established in 1809 as a poor-house) comprises the hospital proper, infirmary, dispensary, lunatic asylum and leper wards. During the year there were 749 admissions, making a total under treatment of 993, of whom 37 recovered, 172 were relieved, 15 unchanged, and 169 died.

PUBLIC HEALTH IN EGYPT.

Annual Report for 1920.¹

OWING to the administrative changes that have taken place in Egypt, and pending the reorganisation of the Department of Public Health, it was thought advisable "to limit the activities of the administration to consolidation of the public health advances already made, and to leave the adoption of future lines of progress to a time when it will be possible with greater certainty to initiate fresh developments in accordance with the subsequent definition of future policy." Two matters, however, had to be dealt with without delay. Unqualified dental practice "was gradually becoming a serious public danger" and is no longer allowed, but exception is made for such practitioners who had been actually in continuous practice for at least ten years, who were admitted to a modified examination; 193 out of 218 candidates passed this test satisfactorily. The other matter was the occurrence of anthrax, traced to the use of shaving brushes imported from Japan. A special law was passed (No. 21 of 1920) forbidding the admission of all shaving brushes unless accompanied by certificates of disinfection from the competent authority in the country of manufacture. Since cessation of hostilities considerable progress in sanitary works has been made by draining marshes and ponds which had been a danger to public health. Moreover, owing to the generous aid of several notables of the country there has been an increased provision of hospitals and medical relief generally; these are, however, still inadequate for the needs of the population. Even in Cairo itself there is no maternity hospital. During the war (1914-19) as many as 44,636 sick and wounded were treated in the Egyptian Government hospitals under the Public Health Administration. The need for this has gradually diminished, and in 1920 there were only 407 military cases in these hospitals, the total in-patients numbering 62,493, compared with 64,704 in 1919. The new out-patients, however, increased from 219,573 in 1919 to 274,557 in 1920, and the major operations performed from 9051 to 12,977. The cost of maintenance rose from 183,141 to 230,612 Livres Egyptiennes (L.E.), while the receipts fell from L.E.18,097 to 15,938. Special wards have been opened in several hospitals for the treatment of ankylostoma, bilharzia, and other worm infections, 14,905 such patients having been treated, of whom 13,000 were infected with bilharzia.

The Population of Egypt.

The calculated population for the whole of Egypt in 1920 is stated as 13,066,600, compared with 12,667,370 in the previous year. (In the annual return for 1920, noticed in THE LANCET of Feb. 25th, 1922, the population (1920) was stated as 13,042,400; the same figure is given for that year in the annual return for 1921.) The birth and death ratios were 42.8 and 28.3 respectively, as compared with 38.0 and 30.0 in 1919. The births varied from 29.2 per 1000 in Aswân province to 47.3 in Asyût, 47.9 in the Fayûm, and 48.5 in Minya. In the 20 principal towns the average birth-rate was 45.3, ranging from 38.1 in Benha to 58.4 in Giza. The average infantile mortality was 23.7 per 1000 births; in Cairo and Alexandria the ratios were 25.1 and 21.7; in Giza and Minya, 30.3 and 33.4; in Ismailia, only 13.1. During the year a complete revision was made of the schedule dealing with *Etablissements incommodes, insalubres ou dangereux*, the regulations regarding their control being "tightened up." The total number of such licensed establishments is now 47,350, of which 18,302 are groceries, 4145 dye works, 3440 cooked food shops, and 2821 butchers. Another very important sanitary improvement is the work of filling in or draining *birkas* (marshy pools); of these 29 were dealt with during 1920, with a total area of 75,179 square metres.

Egyptian Hospitals.

Although the hospital "building programme is sadly behind," and new hospitals and extensions due for completion in 1919 are not yet begun, some progress has been made. Messrs. Thos. Cook and Son, who for years had maintained a small hospital at Luxor, have now generously presented the site, building, and equipment to the Egyptian Government; this will be a great boon to the inhabitants of the district, who number about 45,000. In the country generally there are now 24 hospitals, providing 4091 beds; the in-patients totalled 62,493, and the fresh out-patients 274,557 during the year. An anthelmintic annexe has been attached to the Qasr el Aini Hospital in Cairo, and to the hospitals at Qalyub, Benha, and Mansura; 15,085 patients have been treated for ankylostoma and bilharzia infections. At Qasr el Aini the total in-patients treated numbered 12,610 (with 1204 deaths); in the out-patient department there were 282,970 attendances, of which 119,499 were new cases. Of the medical in-patients 8.6

per cent. suffered from tuberculous disease, 7.5 per cent. from ankylostomiasis, 6.2 per cent. from bilharziasis, and 3.8 per cent. from pellagra. In the bilharzia annexe 931 were treated; of these 875 were for bladder infection, and 29 for bladder and intestinal infection. Intravenous injections of 6 per cent. solution of tartrate of antimony were given on alternate days, commencing with 1 gr., then 1½ gr., then 2 gr. on each subsequent occasion. The minimum quantity found to be effective was 13 gr.²; but, speaking generally, from 20 to 25 gr. are required for an adult, administered during three to four weeks; the drug must be continued "until the ova become definitely opaque, not merely inactive."

An instructive table shows the increase in hospital provision and expenditure since 1912. In that year the total accommodation consisted of 2346 beds, the in-patients numbered 38,887, the total cost of maintenance was L.E.77,992, and the annual cost per bed, L.E.33.2; in 1918 the beds numbered 4543, there were 75,002 in-patients, the total cost was L.E.166,218, and the cost per bed L.E.36.5; in 1919 with 4592 beds and 64,704 in-patients, the total cost was L.E.183,142, and the bed cost L.E.39.8. In 1920, the year under report, with 4091 beds and 62,493 patients, the maintenance rose further to L.E.230,612, and the bed cost to L.E.56.3 per annum. The cost per patient per day was 246 milliemes, as compared with 179 in 1919, and 127 in 1912.

Ophthalmia of a very severe type has always been prevalent in Egypt. Since 1903, when Sir Ernest Cassel made his generous gift of L.E.40,000 for the purpose, treatment has been carried out at 20 hospitals in various parts of the country. "The need for ophthalmic treatment has two entirely separate origins": one is trachoma, and the other "a group of acute contagious ophthalmias which are the main cause of blindness in Egypt." About 15,000 patients who sought treatment at the eye hospitals were blind in one or both eyes—that is, about 14 per cent. of the new patients. The people are, however, beginning to recognise the importance of getting treatment for babies and young children; 40 per cent. of the patients were under 15 years of age, and more than 6 per cent. infants under 12 months. A special ophthalmic hospital is urgently required for Cairo. It should be centrally situated, with 100 beds, and be able to treat 2000 out-patients daily in the summer.

Infectious Diseases.

In regard to infectious diseases there was a very striking improvement. The comparative ratios per 1000 of population are not stated, which omission is to be regretted, but the reduced incidence, as compared with 1919, was 40 per cent. for small-pox, 52 per cent. for plague, 78 per cent. for typhus, and 88 per cent. for relapsing fever. The recorded cases of small-pox numbered 3004. Of these 2720 occurred in the first six months of the year. Vaccination has been carried out energetically; during 1919 and 1920 no less than five and a half million people have been vaccinated—more than a third of the total population of the country. In 1919 Cairo had had 1569 cases: in 1920 there were only 171. In Alexandria the cases dropped from 660 to 411. The only provinces where there was an increase were Asyût and Aswân, where the cases numbered 189 and 187, as compared with 147 and 56 in 1919. The fatality, or case-mortality (either of which expressions is to be preferred to "death-rate" in this connexion) was 26.48 per cent., being higher than in any year of the decennium except 1916, when it was 30.35. Typhus fever decreased from 16,970 cases and 5569 deaths in 1919 to 13,279 cases and 3512 deaths. This was partly due to "disappearance of the movement of labour, which during the war years was undoubtedly responsible for the excessive propagation of this disease and relapsing fever which then occurred in Egypt"; also to early notification and increased skill in carrying out de-lousing procedures. Relapsing fever declined from 3276 cases and 598 deaths to 2876 cases and 430 deaths. The cases of plague fell from 877 in 1919 to 462 in 1920, but the fatality (58.2 per cent.) was somewhat higher than in the previous year (53.9 per cent.); 388 cases were bubonic, 41 septicæmic, and 33 pneumonic. The province of Asyût, where there were 177 cases and 106 deaths, suffered most: after this, Suez, with 87 cases and 55 deaths. Cairo escaped altogether.

The notified cases of malaria numbered 1870, as compared with 1683 in 1919. Of these cases 1594 occurred in Aswân. Nowhere else was there any prevalence. The report states that "a small outbreak at Aswân dam occurred in the month of June, in which some 12 cases were notified. It was found to be due to the existence of some marshy grounds on the east bank of the Nile, in the gardens of the Ministry of Public Works [!]. The ground was filled in and the epidemic

¹ Government Press. Cairo. 1922.² By an unfortunate oversight this is stated (p. 32) as "the minimum effective dose," and "a total dose of 20 to 25 grains for an adult" is afterwards mentioned. "Dose" means strictly the quantity taken at one time.

at once stopped." It is also stated that *birka* filling has been carried out. No comment is made on the fact that 85.2 per cent. of the total malarial incidence in Egypt (1594 out of 1870 cases) occurred in one "locality" (Aswân). In the previous year the ratio had been 77.5 per cent. of the total cases.

Public Laboratories.

The work at the public laboratories continues to increase, the total examinations carried out numbering 18,411, as compared with 15,050 in 1919. The most important researches in the bacteriological section have been in regard to malaria and relapsing fever (6094 specimens), anthrax (1533, mainly shaving brushes), and diphtheria (1083). Of 1380 milk samples, 33.4 per cent. were found to be adulterated. Vaccination was undertaken on a large scale, owing to prevalence of small-pox, and 10,098,720 doses of lymph were issued, nearly double the quantity issued in 1919. This large output is extremely creditable to the staff of the Vaccine Institute, especially as building operations were going on throughout the year, and there was great difficulty in getting suitable calves for vaccine production. At the Antirabic Institute 1035 patients were fully treated; only six deaths occurred "more than 15 days after the treatment was completed." The mortality, or failure, ratio was therefore 0.5 per cent.; 13 other persons died either during treatment, or less than 15 days after completion, giving a gross mortality of 1.8 per cent. The Central and Provincial Medical Commissions examined 24,718 persons for admission to the public service, sick leave, invaliding, &c. Of the 11,553 candidates for admission, 5686 were rejected for medical reasons, the chief cause being defective vision (3668).

This valuable report, which is extremely well printed, is divided into seven sections. The first division of Section I. is signed by Dr. Cathcart Garner, Director-General. No other signature appears, but presumably the entire report is issued under Dr. Garner's authority.

TROOP TRANSPORT.

In the *Military Surgeon* for March, Captain J. D. R. Woodworth gives an interesting account of the methods of the U.S. Army Transport Service in dealing with troop transports, to ensure "cleanly accommodations, minimum danger from disease, and food of unimpeachable quality." His experience was gained in four years at headquarters at Brooklyn. When a transport ship arrives she is examined by an inspector, and further inspections are made while she is fitting out, so that everyone concerned may be instructed in the need for environmental cleanliness as precedent to personal cleanliness; particular emphasis is laid on the way dirt attracts disease-producing insects. All mattresses, pillows, blankets, linen, are sterilised 30 minutes at 260° F., also lifebelts, and carpets, curtains, &c., if required. The plant can deal with 50 to 100 mattresses in an hour. One squad takes these materials to the disinfectant, the trucks are cleaned and sprayed with "insecticide," and a different squad brings the disinfected bedding back to the ship. Messrooms, galleys, store-rooms, pantries are searched for nests of cockroaches and ants, and are sprayed with insecticide, as are also wash-basins, bathrooms, and water-closets. Sodium fluoride, or if these are very small, shellac, is afterwards filled into all cracks. Each sanitary squad consists of a foreman, two mechanics, one sprayer, two torchmen; all are orderlies from the medical corps. They take up all removable fixtures and backs of cupboards, and all bare spaces are brushed and sprayed, all metal work that might harbour insects is burned over by the direct flame of blow-torches. Following this squad come the scrubbers and cleaners who work rapidly, as behind them are always hurrying the painters; then the brasses are cleaned, and the ship is ready for inspection. Food is examined by the national food inspectors, but the port steward and the steward of the ship also examine and may reject anything. If necessary, water is chlorinated after boiling, and water tanks and their linings are frequently inspected. As to the crew of the transport, unless each has been vaccinated recently and inoculated for the typhoid group he must be done now. "Food handlers" (stewards, cooks, waiters, butchers) are examined every six months (as per U.S. Army Regulations) to exclude cholera and typhoid carriers. All passengers are examined within 24 hours of embarkation. Troops are again examined during the first day out, and each must have a spray bath every third day, while passengers are inspected prior to disembarkation. Messtraps are at present washed with soap and rinsed in boiling water, but dish-washing machines are applied for. Refuse is placed in 15 to 30-gallon covered metal garbage containers; there are many, so none are more than half filled, and they are emptied at a special shoot, cleaned and steamed. Ventilation (method not detailed) is carefully watched; the transport surgeon keeps in touch with the chief engineer on this question,

especially in bad weather. As to insects, if food receptacles are always covered these pests cannot get food; nor can rats. Captain Woodworth is justifiably proud of the methods which have already eliminated larger pests. "The Public Health Service, which fumigates the transports, has yet to find the first rat." The insecticide mentioned is made by the Service; its ingredients are not stated, but carbolic acid is mentioned as the best parasiticide.

SPRING-CLEANING AS AN ORGY.

THERE is a tendency nowadays to explain various mental states and conditions of society by a mixture of folk-lore, sexology, and psycho-analysis. Sex, if we may believe modern novels, taken in its widest sense, rules human conduct, and everything is subservient thereto. Like the mythologists of 50 years ago, who saw solar myths in every story of antiquity, so there is a class to-day who sees sex in every human action and in all states of society.

A correspondent, whose gravity we may assume to be only verbal, writes: "Even such apparently asexual matters as motoring and spring-cleaning are deeply committed to sex symbols. In respect of the first, those who have eyes to see can see. Why are all the danger-posts erected by the A.A.A. surmounted by a triangle? The answer is obvious: the triangle is a symbol found all over the world for the female principle in general, and we may recall the anatomical region which the Greeks called Delta Δ. The upright post, as anyone conversant with anthropology knows, is the symbol of the male principle; while both triangle and post are appropriately painted. 'Obscenique ruber porrectus ab inguine palus,' says Horace of Priapus. And again, a most happy find for the sexual anthropologist, these danger-posts are always to be found in the vicinity of schools. The rationalist may believe that this is because children will run in front of motors, but the deeper reason is that children imply, at least in the higher forms of life, the coöperation of the male and female."

These considerations our correspondent holds to be facts which will be allowed by everyone, but he puts forward a hypothesis as to the real meaning of spring-cleaning which he seems to feel needs more support. "I have long wondered," he writes, "as to the origin and meaning of this mystery, but the study of the works of Freud and others have supplied the solution. Spring-cleaning, the orgiastic ceremony which takes place at this time of year, is an obvious example of sex suppression. That it is a merely purificatory function no one who considers the matter can believe; if it were, it would take place in February, the month of 'februa' in the religion of the old Romans, and the one in which the festival of the purification is still held in the Western Church. But spring-cleaning always takes place after Easter—that is to say, close to the vernal equinox, generally in April, when the cycle of reproduction is renewed (cf. Virgil, *Georgics* II., 324). Savages and 'simple lifers,' who are fettered by no scruples, other than an occasional tabu, do not 'spring-clean'; it is only in civilised lands that the ceremony takes place. It is an essentially feminine ritual, and as in the ceremonies of the Bona Dea the presence of men is actively discouraged."

Our correspondent concludes by pointing out that spring-cleaning is a survival of the old days when, under female rule, a ritual was observed according to which fires, save for culinary purposes, were started at a certain date in the year and extinguished on a certain date, when rooms were cleaned and fittings brushed free of the impurities caused by smoke and dust. Between the dates little towards this end was done, the feeling being that the whole domestic environment could be tidied at one period in the spring. To-day arrangements for domestic fires are more perfect, carpets are no longer nailed down, and there is no need to put off cleaning rooms until some distant date; but, he suggests, that the ritual survives as a tribute to that acquiescence in procreancy which is part of human nature.

TO PHOTOGRAPHERS.

THE latest booklet for photographers issued by Messrs. Burroughs Wellcome and Co., entitled "Right Method in Photography," is fairly described as embodying a "simple and scientifically accurate review" of the essentials of success in this exacting craft. The information is equally valuable for the beginner and the advanced worker; exposure, development, intensification and reduction, toning and staining are dealt with in turn, and useful developing timetables are included. The booklet is strikingly illustrated; the cover is a reproduction in photogravure of the base camp of the Mount Everest Expedition, 1922, situated on the Rongbuk Glacier at an altitude of 17,000 feet. Another photograph of historic interest shows the official photographer to the expedition, Capt. J. Noel, at work outside his dark-room tent. The work may be obtained post free on application to Burroughs Wellcome and Co., Snow Hill Buildings, London, E.C. 1.

Certain Points

IN THE DIAGNOSIS AND TREATMENT OF ANGINA PECTORIS.

*An Address Delivered to the Cambridge Medical
Society on May 4th, 1923,*

BY THE RIGHT HON. SIR CLIFFORD ALLBUTT,
P.C., K.C.B., F.R.S., F.R.C.P. LOND.

IN a rather large experience of angina pectoris I have found that competent physicians may have to confess to some uncertainty of diagnosis, and even to occasional errors in discrimination between genuine angina and the various simulations of it. Now there is no error more deplorable than to take a genuine angina for a neurosis; the converse error is plaguy enough. For this reason I have thought it well to consider again the more cardinal points of the diagnosis. If careful attention be given to them the cases of doubt should be very few. On the treatment of the disease I have also something important to say.

At the risk of egotism I must begin with the chief of the postulates concerning the malady, which I laid down about 30 years ago,¹ and which have been confirmed by further experience since. On the continent of Europe and in America these doctrines have made their way rather quickly; among ourselves, after our manner, very slowly. But I observe with some amusement that my medical friends at home are "hedging" one by one. One writer on heart diseases admits, as a curious coincidence, that the symptoms of angina pectoris and of aortitis are identical. Others, forgetful of Ockham's razor, talk of a "dual ætiological explanation." To justify these assumptions, which, I repeat, are necessary for our purpose to-day, I may name, among the authors who have accepted them in France, Josué, Dieulafoy, Wybauw, Vaquez; and in Vienna, Wenckebach, the chief of the First Clinic. In Canada Dr. Klotz and others are with me.² In the United States the "Cardiologists" did me the honour of holding a congress to discuss my opinions, when not a few of the leading speakers accepted them frankly³; while of adverse criticism there was little, if any. That discussion concluded with the statement that I had "made out a good case." Dr. Ingals then, and since, and in private letters to me, has accepted my interpretation; so I believe, do Dr. Babcock and Dr. Hirschfelder. My first eminent convert in America was no less a man than Dr. J. B. Murphy, who died of the disease.

THE CHIEF POSTULATES.

The chief postulates are: (1) That in the very large majority of cases—say 90 per cent.—angina pectoris is due to disease of the thoracic aorta, and especially of its outer investment wherein lie the sensory end-organs that regulate the blood pressures; the few exceptions I cannot discuss now.⁴ (2) That death in angina pectoris is due ordinarily to vagus inhibition; that is, to the shock of the pain. (3) That the coronary arteries and the myocardium have nothing to do with the pain of angina, but much to do with its mortality. In younger persons, in whom the myocardium is healthy, the heart usually survives the inhibition, so that in them angina—as often in the case of syphilitic aorta, for example—may be a terrible if not a mortal disease. I invite you then to entertain for a while these three assumptions, which must serve our purpose for the present, that we may pass on to the diagnosis of the disease; for a disease it is. And by a "disease" I mean no so-called "entity" but a mental concept of a series of symptoms recurring with a fair uniformity.

¹ At the Yarmouth Meeting of Eastern Counties Division of British Medical Association in 1893.

³ See New York Med. Jour., Feb. 15th, 1922.

⁴ See the author's book on Diseases of the Arteries, &c. Macmillan).

Like other diseases, angina may occur in covert or fragmentary forms, or be mimicked by other syndromes. Thus, by reason of latency, partial manifestations, transitoriness, or false resemblances, diagnosis in particular cases may be perplexing. Angina, being often thus transitory or latent, is more common than is generally supposed. As a writer on the subject, my clinical experience may be the larger, but even in its manifest forms there seems to be no lack of cases in private practice, though it seems to be rare in the general hospitals. In illustration of the transitoriness of angina, and so of its being often missed, I will mention some inquiries in our military heart hospitals during the war. There a syphilitic aorta, with or without saccular aneurysm, was no uncommon lesion; in a large ward often as many as half a dozen cases might be found. Of syphilitic aorta in private practice I have watched a few cases throughout in which in the initial stage there was no pain; and in the later stages indeed, pressure effects apart, pain is often absent. The afferent nerves may be destroyed as the spirochaete attacks from without. But on questioning these patients in the heart hospital the majority of them remembered well that they had suffered pain in the past; and when asked to describe it, drew the hand across the upper chest, the common seat of angina pectoris; sometimes adding that at one time it was "pretty bad." But, as I have said, you may give a fairly hopeful prognosis in the angina pectoris of patients, let us say, under 40 or 45 years of age. We must not forget, however, that in syphilis, besides the lesions of the aorta, the heart or its vessels may also be affected.

If, then, a patient under 40 to 50 years of age complains of pain, severe or mild, across the upper thorax, percuss the second right intercostal space and manubrium carefully for any degree of dullness; apply the Wassermann test, and illuminate the aorta by the rays; by these means you may anticipate, and by specific treatment prevent, the extension of an aortic lesion to the valve; a grievous and desperate consequence.

In persons under middle age angina is for the most part of syphilitic origin, probably not mortal unless the heart also be attacked by the infection. Still, cases occur now and then in the course of other infections; most frequently perhaps of influenza, next of rheumatic fever (Poynton and others), and malaria; it may occur in a few other infections, but too rarely for discussion at present. In the severe epidemics of influenza of some years ago I myself saw, and from other physicians heard of, not a few cases of influenzal angina; some of them mortal, and I still see a few sporadic cases. The late Dr. Sansom published three cases with necropsy, when acute aortitis was revealed. But as, in my work on the subject, I have recorded such cases of my own, and quoted others, I will not dwell upon them now longer than to indicate this element of diagnosis, and to urge upon you not to overlook this possible event, one in which prompt and meticulous treatment is imperative. Let the following case suffice as an example: The grown-up son of a colleague of mine in the University, aged about 28, was attacked twice by influenza in 1915. When convalescent from the second attack he began to suffer from severe pains in the chest. Besides his own doctor, he saw three special consultants in London, all of whom, having examined his heart very carefully and found no fault with it, therefore assured him that the pains were only "neurotic," that he was to "take a holiday and buck up." He bucked up, and in spite of pain was advised to persist; the consequence was that in an attack of the pain he died suddenly. Time after time cases of secondary angina are thus airily dismissed as neurotic, until in one or other of them thus wrongly interpreted sudden death rudely reveals the mistake.

Tobacco angina in its intenser degrees is a rare disorder; in my own practice I may have seen some half dozen of the severer cases. A full-grown seizure is a terrible apparition; slight touches of tightness and oppression of the chest are not uncommon, but of little relative importance. In a severe case the pain seems to be agonising. Such is the patient's distress

or panic that, while the attack is upon him, one can hardly get a precise description of the chief seat or distribution of the pain. It may be said to dart all over the chest, to run down one or both arms, and to occupy the cardiac area if it does not begin there; a part, that is, which is rarely the seat of angina proper. The "precordial area" of angina is a figment of the text-books; the primary seat of the pain of angina is in the large majority of cases substernal,⁵ generally under the upper third of the bone. In a few cases it falls to the lower sternum or the epigastrium. Here, then, we gain one point of the differential diagnosis of tobacco angina from angina proper. Another and a more definite distinction of the tobacco disorder is that, whereas in angina proper the sufferer is held in an awestricken arrest, the tobacco patient writhes, tosses, and paces the room in his agony. A third point is that usually in the tobacco cases the heart is irregular, as with extrasystoles or otherwise; whereas in angina proper its action is not disturbed at all, or shows no more than slight vagus retardations.⁶

In another kind of anginiform attack, in acute thrombosis of a coronary artery, the patient is likewise restless. I have offered an explanation of these cases in my book on Arterial Disease and Angina.

DIFFERENTIAL DIAGNOSIS.

It is said that the most difficult cases to distinguish from angina pectoris are the so-called *neurotic*, though I cannot say that personally I have met with much of this difficulty. Angina proper is rare in women. Osler had no recollection of a case; I have seen, and in my book recorded, a few typical and unquestionable cases in women, all of which ended in death. On the other hand, the so-called "pseudo-angina" is frequent among women, more frequent by far than in men. In this malady the pain is correctly defined, as in its principal seat, precordial, and varies from a tiresome submammary ache to a paroxysm of pain, apparently as it lashes about the chest very distressing, often striking very sharply along the intercostal and left anterior axillary lines, and even down the arm. It seems to be a storm in the brachial plexus, intercosto-humeral, Wrisberg, and phrenic nerves. As in the tobacco angina, the patient is not awestricken, but restless and even vociferous. She writhes under the lashing of the pain; she is not silenced by that sense of the uncanny which generally oppresses the victim even of the milder degrees of angina pectoris. The angina patient again is generally, though not always, pallid or pallescent; the pseudo-anginose are flushed in the face. And these patients are for the most part young, or not elderly, under middle age, or but little beyond it, and the attacks may be determined by annoyance, the catamenial period, or other upset. The heart and pulse are not, as in angina proper, tranquil, but throb rapidly, often with an irregular rhythm. The heart may be felt as if leaping out of the body. Palpitation in angina proper does not occur. Between the attacks the physician will fail to detect any sign of disease or degeneration, or none, at any rate, suggestive of cardio-arterial disease. If such signs can be detected the diagnosis must be revised.

The embarrassment of the physician arises when he has to distinguish between simulations of angina and its slighter degrees (angina mitis), or eccentric manifestations of a true angina. These slighter degrees are more common than is generally supposed, and, ominous as they are, not infrequently pass off without critical phases, and the patient lives to die of some other disease. Of its many eccentric and deceptive manifestations, such as epigastric pain suggestive of flatulence or gall-stone, pains in one or both elbows or hands on sharp walking or ascents, and so forth, I have given many examples in my work on the subject. The consultant, or indeed the family physician, may not happen to witness an

attack, especially if it be mild and transient, and he is so far at a disadvantage. In an elderly patient, who described to me momentary sensations of tightness of the chest and arrest while walking, I wished to suspend a verdict of angina; but a medical friend of his told me that while walking with the patient he saw him turn pale, stoop a little, and stop with a look of apprehension on his face. A moment later he stepped forward, saying it was "nothing"; but this description determined the diagnosis; after a while the attacks became more pronounced, and in one of them he died suddenly.

Now it is in this context that I would describe certain mild attacks, far from infrequent in elderly persons, which hitherto have not been disentangled from classical angina. The patients say, and among them I have had three or four medical men who have helped me by careful description of their own cases over long periods of time, that on walking rather quickly a substernal oppression comes on which may amount to a pain. Sometimes it is attended with a slight aching in the deltoid area. In former papers I have given these the name of walking cases. Many elderly persons have told me that if they hasten, as to a train or bus, they feel this substernal tight oppression; indeed, I remember it in my own person when, in past times, I was foolish enough to run. Now is this a covert or rudimentary form of angina? I think not, and for these reasons: Sufferers from angina will perceive a rise in the ground hardly noticed by others, and will not face a hill; but the patients of whom I am now speaking find or notice no difference between level grounds and even steep ascents. When with a medical man thus affected I was discussing the question of retirement from his profession, on account of the stairs he had to climb, he replied that stairs made no difference to him; and sufferers of this class have such immunity. Moreover, although both in angina and in this shadow of angina, the oppression is worst after meals, yet in the false cases recurrence is at all times far more capricious than in the true. It comes and goes. More than one of these patients has told me that if he goes away for a holiday he soon loses the oppression altogether and can walk and climb at discretion. Indeed, even during ordinary work at home the false oppression often disappears for weeks or months and may return, or may not. In true angina there are no such caprices. It stays or it vanishes. My attention has been fixed upon these cases during the last few years only, and, so far, I believe none of them has issued in overt angina. As to the cause of this oppression: it is relieved by passage of wind upwards, but the same is true of real angina. But Dr. Poulton has recently described some experiments, with a colleague, in which a rubber bulb was inserted into the oesophagus and inflated, which inflation gave rise to a substernal oppressive pain described in the same terms as by the patients of the class I have indicated. The explanation may lie not in the distension of an atheromatous and somewhat tender aorta, but rather of the oesophagus by air. Mr. Verdon has given relief in many cases of angina by artificial deflation of the stomach; perhaps some of his cases were of this mimic class? He says also that anginous patients who are distressed by walking may be able to ride a bicycle, an experience which he explains by the relaxation of the abdominal muscles. Of the riding on a bicycle by really anginous patients I know little; elderly men do not often ride bicycles, but I vividly recollect a case of a man a little past middle life, who, after a whole day's fly-fishing with impunity, while bicycling homewards with his son was seized with the first attack of a severe form of angina of which not very long afterwards he died.

Attacks of genuine angina pectoris are apt to occur in the course of another morbid series, which must not be passed over—namely, in the course of high arterial pressures. I do not happen to recall a case in which it occurred as an episode in the course of high pressures due to renal disease, though no doubt it may do so; but of the malady now known as hyperpiesia, it is no very unusual complication, the

⁵ On this contrast with the common submammary ache see Dr. John Parkinson, THE LANCET, April 5th, 1919.

⁶ That in A.P. the phlebograms and E.K.G. are normal, see McIlwaine, Brit. Med. Jour., Feb. 12th, 1920. It is difficult to make these records during an attack.

attacks being the result of stress upon a "fatigued" aorta. My reason for distinguishing this series of morbid events from angina with normal pressures is because in these cases the prognosis is rather less grave, and the malady more manageable. The aorta which could have tolerated ordinary stresses winces under strain. If the aortic blood pressures can be reduced the vessel will probably recover itself, and complain no more. Sir Richard Douglas Powell has stated, in agreement with me, that the phenomena of angina suggest tension of a tender vessel rather than a disease of the heart.⁷ An elderly gentleman, who off and on had been under my care for two or three years for hyperpiesia, one night was awakened by an attack of angina of some severity. This happened two or three years ago; under careful regimen directed to arterial pressures, he has since remained entirely free from attacks. In these high pressure cases put the patient quite at rest in bed, for a week or ten days; during this time the blood pressures will gradually fall, and by appropriate dietetic and other remedies the new peril will probably be averted. But ordinarily in hyperpiesia the anginose symptoms occur on exertion only, and usually, indeed, do not amount to more than a passing substernal oppression. A sudden dyspnoea on mounting hill or stair may be the first manifestation of high arterial pressures of long standing, and more than once such a patient has been sent to me as a case of "angina." Dyspnoea is not a character of angina.

TREATMENT.

This paper is too long already; I must refrain from more clinical chat. What I have to say about treatment can be expressed in a few words. My principle of cure in angina has been, and still is, to treat the case as if it were one of aneurysm—namely, by absolute rest of a duration proportionate to the severity, and the stubbornness, of the case. In a recent case of great intensity and tenacity, in a man of about 65 years of age, I may say that by this method cure has now been established. Not many patients are able, if willing, to betake themselves to bed and to immobility for weeks or months, but those so able have their reward. The patient of whom I speak suffered for the first few weeks so intensely that the mere opening of his bedroom door often brought on an attack; and many were his seizures both by day and by night. He was put to bed; his natural wants were served by the bedpan, his food was made simple and soft, and was carefully administered. Brave, faithful and hopeful through a first period of incessant suffering he then began to feel some mitigation of the attacks in degree and frequency; and after five months of immobility he found himself able gently to move about, and so by degrees to return in a quiet way to his ordinary life. He has not had an attack for a long time past; the sore of the aorta was healed. Happily few cases need so long a restraint as this; few patients perhaps have the easy mind, and the means, the strength of will, and the mental resources, to sustain them through such a discipline. The patient is allowed to read peaceful books and journals, but not to play games nor to entertain guests. Dr. Pratt, of Boston, kindly wrote to me to say that for 10 years past, in cases of angina pectoris, he had followed my method of complete rest with excellent results. There are, of course, many other means, such as the nitrites, to be used as subsidiary to the main purpose; and I have recommended a liberal use of atropine to ward off vagus arrest. But the principle of treatment I have advocated is simplicity itself—namely, so much complete rest, with due modification of diet as may be required for the healing of the injured vessel. Treat angina pectoris then as you would an aneurysm, but with far brighter hope of a successful issue. Of the results of Jonnesco's operation of cervical sympathectomy, in order to throw the aortic afferents out of gear, I know nothing; but the proposal is a reasonable one.

⁷ See THE LANCET, May 1st, 1915.

An Address

ON

SOME GYNÆCOLOGICAL OPERATIONS IN RELATION TO LIFE ASSURANCE.

A Paper read before the Assurance Medical Society on May 2nd, 1923,

By ARTHUR E. GILES, M.D., B.Sc. LOND.,
F.R.C.S. EDIN.,

SENIOR SURGEON, CHELSEA HOSPITAL FOR WOMEN.

In view of the extension of the practice of life insurance and of sickness insurance among women, and of the great increase of gynæcological operations during the last 30 years, it is natural that medical referees of insurance companies should wish to know the influence of such operations on the subsequent health and on the expectation of life. For many years I have been deeply interested in the question of after-results of operative treatment; and it appeared to me that a good deal that I had learnt in the course of my investigations had a direct bearing on the subject. For about 15 years I followed up systematically every case that I could trace among my first thousand gynæcological operations; I wrote to them, interviewed them, and examined them, and made exhaustive analyses of the data obtained. There were 41 operative deaths in the 1000 cases; of the 959 who survived I was able to trace 771, or just 80 per cent. The results were published in 1910 in several issues of the *Journal of Obstetrics and Gynaecology of the British Empire*, and afterwards in book form.¹ Since then I have remained interested in after-results, though I have not been able to follow them up in the detailed, and I may say laborious, fashion in which I studied the first thousand. A great deal of what I now have to say is based on the work just referred to, amplified, and, when necessary, corrected, by subsequent experience of an additional 3000 cases.

OPERATIONS CLASSIFIED.

Obviously the value of the after-history depends primarily on exact knowledge of the nature of the operation; and I had to adopt a classification suitable for this particular purpose. I give it here (Table I.).

TABLE I.

Operation.	Cases.	Cases traced.
1. Unilateral salpingo-oophorectomy—		
A. For tumours	122	98
B. For inflammatory disease	44	29
C. For extra-uterine pregnancy	52	38
2. Bilateral salpingo-oophorectomy—		
D. For tumours	43	33
E. For inflammatory disease	98	63
F. For extra-uterine pregnancy	18	13
G. For uterine fibroids	2	1
3. Abdominal hysterectomy—

¹ A Study of the After-results of Abdominal Operations on the Pelvic Organs. London: Baillière, Tindall and Cox. 1910.

with the number of cases of each kind traced, as it may be convenient to refer to individual groups by their index letters.

[Exploratory Operations Disclosing Malignant Disease too Far Advanced for Removal.]

There is a group of cases, not included in Table I., to which I may make a reference—namely, exploratory operations where malignant disease is found, too far advanced to allow of removal. Experience shows that the expectation of life after such an operation mostly ranges from two to six months. I suppose that these cases would never come before an insurance company, for the first time, after the operation had taken place; but an insurance company might conceivably be interested in a patient for whom such an operation became necessary later on, and the question of the expectation of life might then arise. If that were so, it would be well for the medical officer to bear in mind that even the most experienced operator is not infallible.

I may instance two cases. Many years ago I operated on a patient; I found what I took to be extensive ovarian carcinoma and closed the abdomen. I wrote to her, among the others, when tracing after-results, and expected to hear that she had passed away. Instead, she answered my invitation for an interview by turning up; and she told me, with what seemed like a pardonable pride at scoring off me, that another surgeon had operated and had removed the tumour, and that she was now perfectly well. In the second case my rôle was reversed. One of the best and ablest of the surgeons in the North of England operated and found what he regarded as inoperable carcinoma, and the patient was given a few months to live. Three years later I saw her, and removed what proved to be extensively adherent but benign bilateral ovarian tumours. The patient had become wasted almost to a skeleton; and she gained 30 lb. in weight within three months of the operation.

CASES WHERE DEFINITE OPERATION WAS PERFORMED.

Passing on now to the main subject of this paper—namely, cases in which some definite operation has been done—it will be convenient to take separately two important questions: (1) What is the expectation of life after abdominal operations? (2) What is the state of health after these operations?

1. What is the Expectation of Life After Abdominal Operations?

For an attempt to formulate an answer to this question we must obtain the most exact information available as to the conditions present at the time of operation.

Carcinoma.—The most important point is whether malignant disease was present and where. After ovariectomy for ovarian carcinoma, even if the growth appears to be completely removed at operation, there is an appreciable risk of recurrence. I cannot give precise figures for this; I can only state my impression that the risk may be put down as about 25 per cent. In the case of hysterectomy for cancer of the cervix, the risk of recurrence is much higher. Many statistics have been published, and they vary enormously; moreover, the value of the data is seriously impaired by the failure of many operators to distinguish between the results of operations in early cases and those in advanced cases. My belief is that if we put down the recurrences in early cases as 30 per cent. and those in advanced cases as 75 per cent., we shall not be over-estimating the risk. On the other hand, hysterectomy for cancer of the body of the uterus has a much more favourable outlook; judging from my own experience, I should say that the chance of recurrence may be put down as 10 per cent. for all cases, with a rather higher figure for the more advanced and a lower figure for the early ones. After a hysterectomy for chorion-epithelioma the chances of metastasis and recurrence are very great, and such a patient must be regarded as a "bad life." Sarcoma of the uterus

is much rarer than carcinoma; and I know of no data concerning its recurrence. My impression is that in this respect it might be classed with carcinoma of the body of the uterus.

Benign Tumours.—When bilateral ovariectomy has been done for benign ovarian cysts, there is no fear of recurrence, and the expectation of life may be regarded as being nearly as good as it is in the case of the average normal woman. I put in the qualification "nearly" for two reasons. In the first place even pathological diagnosis may err; and I have known several cases where the pathological report on ovarian tumours removed pronounced them to be benign; yet the patient developed obvious abdominal recurrence of a malignant character later on. It must be admitted that ovarian tumours sometimes show histological characters on which experts may express quite divergent views. Thus a cystic adenoma may closely resemble an adeno-carcinoma; a benign papilloma may be very difficult to distinguish from a malignant one, inasmuch that the sequel alone shows which it is. If there is no recurrence we say it was benign; if there is recurrence we say it was malignant. I recall also a case of a huge ovarian fibroma, weighing 30 lb., which I removed from a patient aged 60; when I showed the specimen with slides, at the Royal Society of Medicine, some members of the pathological committee expressed a confident view that it was sarcoma. Others took the same view as I did, that it was fibroma. The patient lived over 13 years after the operation, and died recently without any signs of recurrence.

I should certainly advise insurance medical referees to be cautious in accepting as a first-class life a patient who has had an ovarian papilloma removed.

My second reason for the qualification of "nearly" is that a patient who has had an abdominal operation of any kind has a small, but appreciable, liability to further trouble. I shall deal with this more fully when speaking of after-health. A patient who has had a unilateral ovariectomy done carries with her the two risks just considered—that of incorrect diagnosis, and what I may term the "general operative sequela risk." She runs a third risk, due to the fact that she still possesses an ovary. This point also will be dealt with more fully under "after-health." Hysterectomy for benign conditions, such as uterine fibromata, uterine fibrosis, and chronic metritis involves no consequences beyond the "general operative sequela risk," and even this is less than is the case after other operations. Therefore, as far as this factor is concerned, I should consider that such a patient could quite well be accepted as a first-class life.

Tubal Inflammatory Conditions.—In this category we may include not only salpingitis, pyosalpinx, tubo-ovarian cysts, and tubo-ovarian abscess, but also cases in which an operation has had to be undertaken for a ruptured extra-uterine pregnancy. In all these cases the "general operative sequela risk" is higher, because the inflammatory condition exaggerates the liability to trouble arising from adhesions. I have met with or known of several cases of intestinal obstruction following operations for the removal of pus-tubes, after an interval of one to three years. When the operation is unilateral there is a quite considerable liability to subsequent trouble in the remaining appendages. It can be stated, however, that any sequel of the one kind or the other is likely to show itself within the first five years after operation; and if at the end of this time the patient feels well and the pelvic condition appears to be normal, I should regard her as eligible, *ceteris paribus*, for acceptance as a first-class life.

All the above operations involve the removal of organs, and one further general observation may be made with regard to them—namely, that operations for the removal of the uterus or of both ovaries eliminate an important risk to which the average normal woman of child-bearing age is liable—namely, the risk of child-birth. I suppose that from the insurance point of view a woman who has had this factor eliminated would, other things being equal, be

accepted for insurance purposes on much the same footing as a man.

Expectation of Life After Conservative Procedures.—One class must be taken by itself—namely, myomectomy for fibroid tumours. Here the general operative sequela risk is increased by the possibility that other fibroid tumours may develop. The remaining conservative procedures can be grouped together; they would include operations for the rectification of displacements, salpingostomy, and the resection of ovarian cysts. The general operative sequela risk in all these cases is low, and the patients may be considered, from the insurance point of view, as being practically normal women.

2. What is the State of Health After Abdominal Operations?

General Health.—In my investigation on after-results I made careful inquiries as to the general health after operations; I grouped the replies into three categories: (1) general health very good; (2) health moderate, but better than before operation; (3) health poor, or worse than before operation. The insurance referee is not interested in the comparison of the health before and after operation; he wants to know only the present standard of health. I had comprehensive tables showing the percentage of cases in each group, worked out for each one of the different types of operation (A to U). In Table II. I shall condense results.

TABLE II.

Health.	A.B.C.		D.E.F.M.O.		H.I.K.L.N.		Q.S.T.		Total.	
	No.	%	No.	%	No.	%	No.	%	No.	%
Very good.	141	65.4	110	77.4	132	73.4	143	76.4	526	72.5
Poor or moderate.	75	34.6	32	22.6	48	26.6	44	23.6	199	27.5
Total ..	216	—	142	—	180	—	187	—	725	—

It will be seen that of 725 total cases in which data were available, 526, or 72.5 per cent., expressed themselves as being in very good health. In individual groups of operations the results varied; and it is striking that the highest percentage of cases of very good health occurred in the cases where the appendages of both sides were removed; whilst the lowest percentage was in cases where the appendages were removed on one side only. This seems to show that by saving the appendages of one side, while we preserve function, we add to the possibilities of subsequent ill-health. The conservative operations, ventrofixation and myomectomy, have also a very high percentage of very good health; and the operation of hysterectomy for benign conditions is not far behind.

State of the Memory.—This is a minor, but none the less interesting point. Years ago I came across the statement that the memory was sometimes affected after operations; and though my impression was that this must be very rare, I questioned my patients closely. I was surprised, when working out the figures, to find that the memory appeared to be

TABLE III.

Operation.	Average duration.	Memory affected (per cent.).
Hysterectomy for carcinoma ..	1—1½ hours.	50
Removal of inflamed appendages ..	½ hour.	32
Hysterectomy and myomectomy for fibroids ..	½ hour.	27
Ovariectomy ..	20 min. to ½ hour.	26
Hysteropexy ..	½ hour.	18

affected in about 25 per cent. I divided my data into five groups according to the type of operation; and it then seemed evident that the factor that had the most influence was the duration of the operation.

This will be made clear by setting out in parallel columns (Table III.) the average duration of operation in the five groups, and the percentage of cases in each group in which the memory was affected.

General Operative Sequela Risk.—I have referred to this when discussing the expectation of life; and it will be profitable to look into it in more detail. Twenty-three patients of those that I traced died later: ten from recurrence of malignant disease, two from intestinal obstruction, one from generalised miliary tuberculosis; these 13 may be said to have died of sequelæ of the operation. The remaining ten were from independent causes: two of pneumonia, two by suicide, and one each of carcinoma of the breast, carcinoma of the sigmoid, carcinoma of the rectum, cholera, uræmia, and pulmonary oedema. At the time of my investigations, in 1910, I had records of 64 cases in which further operation was required. For the purpose of this paper I have gone over the cases again and traced an additional 20 cases from among the same original cases investigated, in which operation was required after those results were published. This makes altogether 84 cases; and it will be instructive to consider them in relation to the nature of the first operation (Table IV.).

TABLE IV.

Operation.	Cases.	Later operation.	Percentage.
Unilateral salpingo-oophorectomy ..	98	17	17.3
Tubal disease or for tubal pregnancy ..	67	17	25.3
Bilateral ovariectomy for tumours ..	43	3	7.0
Bilateral salpingo-oophorectomy for tubal disease or for tubal pregnancy ..	94	16	17.0
Hysterectomy for fibroids and fibrosis ..	186	7	3.7
Myomectomy ..	40	7	17.5
Operations for uterine displacements ..	225	17	7.5
Total ..	753	84	—

We must distinguish between operations undertaken for conditions which are direct sequelæ of the first operation, and those that are necessitated by conditions independent of it.

Unilateral Ovariectomy.—Three patients developed a hernia of the scar: one had intestinal obstruction, presumably from adhesions; and three developed malignant disease: one of these had a large inoperable tumour, and a colotomy was done; the second had a large adeno-carcinoma of retroperitoneal origin, weighing 4½ lb.; and the third had recurrent growths in both iliac fossæ and in the scar. In all three cases the tumour first removed was regarded as innocent, and they illustrate forcibly the caution previously uttered as to the possibility of pathological error. The scar hernias and the intestinal obstruction are direct sequelæ; two of the recurrences occurred within a year, and may also be regarded as sequelæ. The retroperitoneal adeno-carcinoma is more doubtful, as it did not appear until seven years had elapsed. Of the remaining ten cases, one had an extra-uterine pregnancy on the other side; five developed a second ovarian tumour; two had tubal disease of the other side; and two required hysterectomy for fibroids. The net result in the groups is: three scar hernias; four other sequelæ; and ten independent conditions.

Unilateral Salpingo-oophorectomy.—Among these cases there were two scar hernias; and there were two other sequelæ in the form of an infected stump adherent to bowel. Of the 13 independent conditions, two operations were for a second ovarian tumour; four for tubal disease on the other side; four for tubal pregnancy on the other side; one each for uterine fibroid, uterine fibrosis, and uterine displacement. It will be noticed that, in these two groups together, out of 165 cases there were no fewer than 18, or 10.9 per cent., in which there was trouble later on in the remaining ovary or tube—namely, seven ovarian tumours, six cases of tubal disease and five of extra-uterine pregnancy.

Bilateral Ovariectomy.—Of the three subsequent operations, two were for scar hernia, and the other was for a necrotic tumour incarcerated in the pelvis among dense adhesions. Its necrotic character made it impossible to determine its nature; we may assume that it was an independent condition, rather than a sequela.

Bilateral Salpingo-oöphorectomy.—Here there were five cases of scar hernia and five other sequelæ—namely, intestinal obstruction, an operation for the separation of adhesions, and three cases of an inflammatory focus in the stump. The independent conditions were: Uterine fibroids, two cases; cystic degeneration of one ovary that had been preserved, two cases; hysterectomy for fibroids; and hysterectomy for carcinoma of the cervix. In the last case the hysterectomy was done 26 years after the previous operation.

Hysterectomy for Fibroids.—Four of the seven later operations were for sequelæ—namely, one scar hernia; a case of separation of adhesions; an abscess of the cervical stump, causing an abdominal sinus; and an infection of the cæcum leading to perforation, and necessitating an enterorrhaphy. The independent conditions were a case of ovariectomy; a gastro-jejunoscopy for duodenal ulcer; and an exploratory for what appeared to be carcinoma of the sigmoid and bladder. This patient lived for years after in good health, so the diagnosis became doubtful.

Myomectomy.—There were two scar hernias in this group. Of the remaining five operations, four were hysterectomies for recurrence of fibroids; these must be regarded as coming into the category of sequelæ. The other was a hysterectomy for fibrosis, which was an independent condition.

Operations for Displacements.—This group presented four scar hernias and five other sequelæ—namely, refixation of the uterus for recurrence of the displacement. The eight independent operations were as follows: Two for appendicitis, two hysterectomies for fibroids, a double ovariectomy, a single ovariectomy, a case of tubal disease, and an exploratory operation for what proved to be an inoperable carcinoma.

We may now try to express statistically the risk that further operative procedures may be necessary. It is certain that the general operative sequela risk is more definite than the risk of independent conditions requiring operation; but presumably, from the actuarial point of view, they must all be taken into consideration. The preceding results are expressed in Table V.

TABLE V.

	Cases.		Scar hernia.		Total operations for sequelæ.		Operations for independent conditions.		Total.	
			No.	%	No.	%	No.	%	No.	%
Unilateral ovariectomy	98	3	3.0	7	7.1	10	10.2	17	17.3	
Unilateral salp. oöph.	67	2	3.0	4	6.0	13	19.4	17	25.3	
Bilateral ovariectomy	43	2	4.6	2	4.6	1	2.3	3	7.0	
Bilateral salp. oöph. . .	94	5	5.3	10	10.6	6	6.4	16	17.0	
Hysterectomy for fibroids	186	1	0.5	4	2.1	3	1.6	7	3.7	
Myomectomy	40	2	5.0	6	15.0	1	2.5	7	17.5	
Operations for displacements	225	4	1.7	9	4.0	8	3.5	17	7.5	
Total	753	19	2.5	42	5.5	42	5.5	84	11.1	

Salp. oöph. = Salpingo-oöphorectomy.

It would thus appear that for abdominal operations in general the operative sequela risk is the same as the risk of further independent conditions requiring operation, each standing at 5.5 per cent.; and the total risk is 11 per cent. But with some operations the risk is very high, being as much as 25 per cent., or 1 in 4, for unilateral removal of diseased appendages; and 17 per cent., or 1 in 6, for unilateral ovariectomy, bilateral removal of diseased tubes, and myomectomy; whilst at the other end of the scale

the risk after hysterectomy for benign conditions is 3.7 per cent., or 1 in 15; and it is about twice as great after bilateral ovariectomy and operations for displacement.

It is perhaps necessary to bear in mind that if we took any thousand average healthy women of 25 years of age, and could trace their lives for 20 years, we should find an appreciable number at the end of that time who had had to undergo operations of different kinds. If we could obtain figures representing this primary risk and deducted the numbers from the figures in my tables we should get a close approximation to the real risk of further operative procedures that results from abdominal operations. I may further point out that the figures that I have given probably indicate the maximum risk; for they refer to my earlier cases. With improvements in operative technique, and especially the greater perfection of asepsis, the incidence of scar hernias and of sinuses due to septic foci has greatly diminished, and I have no doubt that if I could trace the detailed history of my last thousand cases, the number requiring subsequent operation would be markedly less.

SUMMARY.

I may summarise my observations as follows:—

Health after Operations.—About 70 per cent. of patients regain normal health. The highest proportion is found in cases of conservative procedures and of complete removal of organs. Unilateral operations on the uterine appendages show the lowest proportion of complete recoveries, the chances of complete cure being subordinate to the preservation of functions of womanhood. There is a disturbance of the nervous system, shown especially by the affection of memory, and in most cases temporary, in a proportion of cases, varying from 18 per cent. of cases where the operation was of short duration to 50 per cent. in the case of long operations. There is a risk that further operations may be required, which may be put down as a 10 per cent. risk, comprising direct sequelæ of the operation and independent conditions in about equal proportions. The risk is greatest after operations for inflammatory disease of the tubes and after unilateral operations on the tubes and ovaries; and it is lowest after the operation of hysterectomy for benign conditions.

Expectation of Life.—Cases of operation for malignant disease must be regarded as bad lives, the risk of recurrence varying from 10 to 75 per cent. After operations for inflammatory disease the expectation of life is fairly good, but it is impaired by the liability of sequelæ. Patients who have had benign tumours removed may be considered as good lives, as the chance of complications that may lead to a fatal result is negligible. Lastly, patients who have had operations that prevent further pregnancy have had an adverse factor in the expectation of life eliminated.

CHELSEA HOSPITAL FOR WOMEN.—The fifty-second annual meeting of the governors was held on April 24th, Sir Louis A. Newton presiding. The Council's report for the past year stated that the number of patients treated was 848, an increase of 100 compared with 1921. This increase had been effected by closing one floor at a time for annual cleaning instead of both together, and it was the chief factor in a reduction of the cost per patient per week from £4 2s. 7d. to £3 9s. 2d. During the year 533 major and 302 minor operations were performed. The out-patients' fee had been reduced from 2s. to 1s., except for the first attendance. Only half the beds can be used for patients until the staff can be moved from the others to the proposed nurses' home. A sum of rather more than £30,000 is needed for building the home; £18,000 is in hand. The chairman, in moving the adoption of the report, made a strong appeal for the balance required for the nurses' home fund, stating that it would enable the hospital to treat some 700 additional patients yearly. A paying home for patients no longer able to pay the high fees of nursing homes was greatly to be desired and could be built in the hospital grounds. The Voluntary Hospitals Commission and the Combined Hospitals Appeal had done much to restore the financial position of the hospital, but continued efforts were needed.

THE TREATMENT OF THE CLAVICLE FRACTURED BY INDIRECT VIOLENCE.

BY FRANK ROMER, M.R.C.S. ENG.,
CONSULTING SURGEON TO THE JOCKEY CLUB.

BEFORE describing the method I adopt in the treatment of such fractures of the clavicle as have been caused by indirect violence, it would be as well to give a short description of the clavicle and scapula, and a brief account of their mechanics.

The clavicle is curved in shape, so that the inner two-thirds are more or less rounded in form, while the other third is flattened from above downwards. The inner segment is curved to enable a different portion of that arc to impact on the upper surface of the entire length of the first costal arch, and as it ascends gradually upwards becoming more abrupt posteriorly when the shoulder is carried from an extreme forward to an extreme backward position. In the various positions of the shoulder the clavicle transmits force in a vertical direction to any portion of the entire first costal arch and, if sufficient downward pressure be exerted, the clavicle impacts and transmits pressure to a part of the second costal arch. The inner end of the clavicle is held down by powerful ligaments, and forms the fulcrum of a lever, the length of which corresponds to the entire clavicle. The outer third, which is thrown forwards in order to bring the scapula and arm into a useful working relationship with the thorax, is flattened in consequence of the strain exerted upon it posteriorly by the trapezius, and anteriorly by the deltoid, ossification taking place in the line of strain. This portion of the bone, besides performing the purpose of a lever, serves as the junction of the deltoid and trapezius muscles, and is directly continuous and identical in function with the acromion and the spine of the scapula. The two bones—namely, the clavicle and the acromion—move on one another, on an inclined plane, in order to enable the glenoid cavity to be brought into relationship with the humerus and clavicle. The relationship of the scapula to the clavicle and humerus is that of an intermediary, the scapula being to some extent a part of the clavicle, with which its spinous process is continuous in direction and function. The scapula is supported partly by muscles, and to a far greater extent by the powerful coraco-clavicular ligaments, which connect the base of the coracoid process to the clavicle. It will be seen that should a fracture of the shaft of the clavicle take place proximal to the coraco-clavicular ligaments the scapula, lacking the stay of a sound clavicle, is rotated forwards by the action of the serratus magnus and pectoralis minor muscles, by its own weight, and by that of the arm which helps in exaggerating the displacement of the scapula and outer fragment of the clavicle in a downward, forward, and inward direction. The inner fragment of the clavicle is kept in position to some extent by the rhomboid ligament, its outer extremity being displaced upward by the action of the sterno-cleido mastoid muscle and by the elastic pressure of the first costal arch, the shoulder dropping forwards and downwards.

Principle of Replacement of Scapula.

The principle upon which treatment must be based is the replacement of the scapula in its normal relationship to the clavicle and thorax, the tilting of the inner fragment being taken into consideration. While the placing of the patient in the supine position tends to do this, it only effects it very imperfectly because of the tilting alluded to. It is a common fallacy to imagine that accurate apposition of the clavicular fragments can be secured in this way. The method generally adopted is to endeavour to so fix the arm in position in relation to the thorax that a thrust in an upward, outward, and backward direction is exerted through the humerus on the scapula. The

objections which I take to this method are that it does not effect the purpose for which it is intended, that it puts the arm out of commission for a long time, that the muscles waste and the joints become stiff, that union is delayed, and that the position, if the treatment is carried out with sufficient thoroughness to serve any useful purpose, is uncomfortable and painful.

Technique.

The method which I adopt is to secure as thoroughly as possible the proper relationship of the fragments to one another by fixing the scapula in position by strapping, the arm being left quite free. By this means recovery is very rapid and painless, the arm suffers no depreciation in function, and union takes place rapidly and in good position.

The common seat of fracture is in the middle third of the bone, and the position assumed by the patient is typical of the lesion. He stands with his head bent down towards the fractured side, in his effort to relax the pull of the sterno-cleido mastoid of the inner fragment, whilst the hand of the sound arm supports the elbow on the damaged side, in order to relieve the drag of the arm on the outer fragment. The principle involved in this method of treatment depends on the control of the outer fragment by means of the intermediary, the scapula. In order, therefore, to reduce the deformity, raise the arm on the injured side to a right angle with the body. This brings the outer fragment up to the level of the inner fragment. Stand behind the patient and draw back both shoulders firmly, so that the scapula is pushed back as far as possible, the arm still being kept raised at a right angle. Having effected reduction of the deformity in this manner, apposition of the fragments is secured by fixing of the scapula in the position in which it now lies. Do this in the following manner. With the injured arm still raised at a right angle (Fig. 1), place a thin layer of Gamgee tissue or cotton-wool in the axilla. Then fix the end of a long strip of adhesive plaster to the top of the shoulder-joint, just over the acromion, and bring it up under the axilla to the front where it crosses over the top of the shoulder at the acromial end of the clavicle. This strip, which encircles the shoulder-joint, is brought diagonally across the scapula to below its angle. Take a second strip of plaster, about 1½ in. in width, and start from just above the nipple and bring it with firm pressure over the clavicle to below the angle of the scapula (Fig. 2), much in the position of an ordinary brace. Apply a third and fourth piece in the same way, slightly overlapping each other, and covering the entire surface of the clavicle (Fig. 3). Lower the arm gently, and allow the patient to dress himself in the ordinary way. No support is required beyond that obtained by means of an ordinary sling, which is worn for the first two days to prevent the weight of the arm causing discomfort. The use of the arm should be restricted to underhand movements, though one rarely finds much desire on the part of the patient to do more. The services of a skilled masseur are obtained, and the injured parts are massaged daily for at least a week. I should mention that the movements of massage can be effectively performed over the plaster. At the end of about ten days the sling can usually be discarded, and the patient encouraged to employ the arm for more general use. The strapping should be renewed at the end of the first four days, and again from time to time as occasion demands. By the end of a fortnight all movements are usually possible, but care should be taken to avoid the increase of undue strain, as in lifting or pushing heavy weights. The parts should be kept supported by strapping for at least three weeks, even though no pain be experienced on movement. The advantages to be gained by adopting this method over the mode of treatment generally in use are firstly, entire freedom from that pain which is caused by keeping the arm and hand rigidly immobile, since the cramp during the first few days is often intense and far exceeds any suffering that may be experi-

enced at the seat of fracture. In addition, the subsequent stiffness of the elbow and forearm is no longer experienced, and as the arm is in use muscle wasting is avoided when the union is complete. The patient is able to dress himself normally during the entire period of convalescence, and can use the arm on the injured side for writing, feeding, and such simple actions, without fear of harm. Again, the period of disability is considerably lessened. The average period of disability according to other writers

strapped, and massage ordered. Two days later the pain had entirely gone, and the arm moved comfortably. Within 20 days he was able to ride gallops, and rode in a race a week later.

CASE 6.—Flat race jockey, fractured his left clavicle at Folkestone, and was attended to on the course. Seen same day as accident. Bandages had slipped, and the man was in great pain. Strapping applied, and massage ordered, which speedily relieved the pain. Restrained in three days. Uneventful recovery; patient was riding within three weeks of the date of injury.

FIG. 1.

First strip of plaster in position, with cotton-wool in axilla.

is put down as being between six and eight weeks. The average period in 20 of my cases, taken at random, was 20 days. When possible the patient should spend 12 hours flat on his back, especially where reduction is difficult, as the scapula being unable to rotate forward, the bones gradually drop into position and the deformity lessens.

A Series of Ten Cases.

I quote various cases as examples:—

CASE 1.—Amateur rider, steeplechasing, had a severe fall, the horse being killed. Fracture of left clavicle sustained, with much deformity. Reduced and put up by me the same evening, massage being ordered. A recent letter from this patient states: "I did the hat trick with my first three rides 15 days after the accident, on C—, B—, and A—, two of them very hard pullers too." The shoulder was kept strapped for another three weeks.

CASE 2.—Steeplechase jockey, fractured left clavicle at Sandown. Displacement very definite at the junction of the inner and middle third. Treatment by strapping and massage. He won a hurdle race within 14 days of the injury, and continued to ride as before.

CASE 3.—Fell whilst "schooling" and fractured left clavicle. When seen that evening was in great pain, as he was confined in bandages according to Sayre's method. Removal of these with substitution of strapping entirely relieved the pain. Massage ordered. Was riding over fences within 21 days, and won a race.

CASE 4.—Flat race jockey, fell during a race at Windsor and fractured the right clavicle. Was attended to on the course, and fracture put up in usual method. I saw him on the day of accident, strapped the shoulder, and ordered massage. Rode and won a race 17 days after the injury without ill-effects. He had some pain as the horse "yawed" at the post. Was strapped afterwards, but continued to ride regularly.

CASE 5.—Flat race jockey, sustained complete fracture of the left clavicle from fall of his horse in a race. I saw him six days after the accident; he was then in considerable pain, his arm being bound to the side in the orthodox manner. Deformity of bone still present at junction of middle and outer third. Bandages removed, fracture

FIG. 2.

Second and third strips of plaster in position.

CASE 7.—Fell whilst riding in steeplechase and fractured right clavicle. Seen day following accident. Had been put up at neighbouring infirmary in usual manner. Right hand and forearm swollen, and bruising over the seat of fracture. Fracture comminuted. Rest in bed, flat on his back for a few days advised. The bandages being removed, the shoulder was strapped and massage ordered. Pain in the forearm disappeared after the first day's massage, and swelling at seat of fracture gradually subsided; he was up and about in a week's time. He was perfectly sound in three weeks, but did not ride steeplechases for a month.

CASE 8.—Flat race jockey. Sustained complete fracture of right clavicle from his horse falling dead at Lincoln. Seen day after accident. He had been put up in the usual manner on the course. Complained of great pain in hand and forearm. The bandages were removed and strapping applied, and massage ordered. He made a normal recovery and was riding within 18 days of the accident.

CASE 9.—Steeplechase jockey, fell in hurdle race at Gatwick. Fractured right clavicle. Seen same day. Attended on the course. Comminuted fracture caused great pain; patient had a lump on the forehead. He was dazed, and vomited in the consulting-room. He was kept flat on his back for five days, the fracture being strapped and massaged as usual. At the end of a week, the effects of the concussion having passed off, the patient was allowed to get about as usual. He made an uneventful recovery, though the risk of falling prevented me from permitting him to participate in races for a month.

CASE 10.—Flat race apprentice, fell and fractured clavicle. Seen day after accident. Had been put up on the race course in the usual manner. Considerable displacement, much bruising, and in considerable pain. Patient was kept on his back for two days and shoulder strapped. Twenty-three days from date of accident I received a letter from his master saying that the boy was apparently sound, and had been riding as usual.

Commentary.

I have selected those cases whose subsequent history I have been able to watch. The quick recovery the majority have made is partly due to the healthy life they have to lead. The strain on

both shoulders in riding races, or fast gallops, is very severe, and for that reason I have taken riding as a test of soundness. All of these cases I have quoted showed unmistakable evidence of the lesion, with typical displacement, whilst in some the deformity was very considerable. It has been suggested that the freedom allowed the arm might tend to increase the deformity, or even lead to non-union. The results, however, as regards the ensuing deformity are no worse and no better than those obtained by

FIG. 3.

Four strips in position, covering entire surface of clavicle; massage can be performed over the plaster.

other methods, whilst in some 200 cases treated in the manner described I have seen only one case of non-union. This case, a jockey, was brought to me two days after the injury. He had removed the bandages within a few hours of being put up on the race course, and had used a sling. The inner fragment was lying uppermost, parallel with the sternomastoid, and the outer fragment showed every inclination to come through the skin. He had, it appears, been kicked by another horse on the clavicle, after it had been fractured by his fall. He was kept five days flat on his back, and I was able to bring the fragments into fair position. The radiogram showed extensive comminution, and a considerable gap existed between the two fragments. Sir Arbuthnot Lane saw him with me, with a view to operative measures, but he decided to leave it alone. The man now has fibrous union, with palpable movement at the seat of fracture. He has a strong, sound arm, and is still following his profession of steeplechase jockey.

I am convinced that experience will soon lead others to adopt this method, in preference to that so commonly employed, but as Zollner said: "The ancient wall of belief requires much siege artillery for its demolition," and a belief in the teachings of our student days is not easily upset.

Seymour-street, W.

OPHTHALMIC HOSPITAL, JERUSALEM.—The report of the Committee for 1922 records an extension of the hospital buildings which was opened for work last July, and by means of which the work in the out-patient department has been greatly facilitated. The number of new cases seen was 12,651, and the number of new cases admitted to hospital was 1268. The great bulk of the work, as in all eye hospitals in the East, consists in the treatment of trachoma and of acute conjunctivitis, but the refraction cases show a steady increase in numbers. In 1919 there were only 269. Last year the number relieved with spectacles had risen to 1148.

AN INVESTIGATION OF RENAL FUNCTION IN PATIENTS WITH RETINITIS AND HIGH BLOOD PRESSURE.

BY ARTHUR W. M. ELLIS, M.B. TORONTO,
M.R.C.P. LOND.,

AND

J. R. MARRACK, M.B., B.CH. CAMB.
(From the Medical Unit and the Hale Clinical
Laboratory, the London Hospital, E.)

RETINITIS associated with high blood pressure and renal disease has long excited the interest of physicians. The importance of the condition in diagnosis and prognosis is well known, but the nature of the process, its cause and method of production, is very imperfectly understood. For this reason we have thought it might be of interest to examine the data of those cases of retinitis in the London Hospital in which the results of investigation by the newer methods of estimating renal function were available. The number of patients with retinitis so examined was 21, but the result in two of these we have discarded, as they were examples of the condition occurring in pregnancy, a retinitis generally recognised as having a different course and significance. This report consists, therefore, of an analysis of 19 cases.

Scope of Inquiry.

It is to be clearly understood that in this paper we are not dealing with acute nephritis, subacute nephritis, or chronic nephritis with gross oedema (chronic parenchymatous nephritis). By subacute nephritis we mean those cases in which, following an acute attack, symptoms fail to clear up and the patients either pass into a state of chronic poor health or suffer from repeated exacerbations of the acute condition. All these forms of nephritis may lead to the occurrence of retinitis. No example, however, of any of these forms happened to occur in this series, and we are not concerned with them. They are all easily separated, by purely clinical methods, from that group of cases with high blood pressure, albuminuria, and little or no oedema somewhat indiscriminately labelled "chronic interstitial nephritis" and "cardio-renal disease," to which all our 19 cases belong.

Differentiation of Arterio-Sclerotic and Renal Retinitis.

During the course of the collection of these cases a discussion took place at the Royal Society of Medicine on the differentiation of arterio-sclerotic and renal retinitis.¹ In considering the results our first proceeding, therefore, was to separate our cases into two groups, one in which gross disturbance of renal function was evident and the other in which no such gross disturbance was found. The particulars of the cases in the two groups so separated are shown in Tables I. and II. Let us now analyse the data of these two groups of patients separated, it is to be understood, solely on the results of the tests of renal function. In Table I. are listed the particulars of nine patients showing gross disturbance of renal function. In all, the blood-urea was much increased, the phenolsulphone-phthalein excretion markedly diminished, and the urea-concentration test showed very feeble power to concentrate urea. Fixation of the specific gravity of the urine occurred in six of the seven cases in which this examination was carried out. Table II. shows the particulars of ten cases in which no such gross disturbances of renal function were found. In only two of these is the figure for blood-urea above the normal; phenolsulphonephthalein excretion, while generally diminished, is notably different from the figures in Table I., and the urea-concentration test, in striking contrast to the findings in the other group, gave in only one case a figure below the normal

¹ THE LANCET, 1922, ii., 1222, 1275.

2 per cent. In no case did fixation of the specific gravity of the urine occur.

Age and Cause of Death.

Such are the data on which separation into the two groups was made. A further analysis of the findings in these tables reveals, however, other striking differences, the most important of which, in our opinion, are the age of the patients and their mode of death. The average age on admission of the patients listed in Table I. was 33, in Table II. 49, a difference of 16 years. The mode of death was also strikingly different. All nine cases in the first group died within four months of admission to hospital. In one the mode of death is unknown; one died with cardiac failure and broncho-pneumonia. All the remaining seven died in uræmia. On the other hand, of the ten patients in the second group five are still alive at the time of writing, the longest time since admission being, however, only six months. Of the five who

two quite sharply defined groups.² The first of these consists of relatively young individuals with high blood pressure and gross loss of kidney function in whom death rapidly ensued usually in uræmia. The second consists of older individuals with still higher blood pressure, but less disturbed renal function, in whom life was relatively prolonged, and death, when it occurred, was from cerebral hæmorrhage or heart failure. What deductions can we draw from our analysis? What significance can we attach to this grouping?

There seem to be two possibilities: (1) that the two groups of patients represent different stages or different forms of the same pathological process; (2) that they result from different pathological conditions. It may be argued, for example, that the cases in Group 1 show merely the advanced stage of the condition seen in its earlier stage in Group 2. If this is the case, how does it come that the average age of the patients in Group 1 is 16 years younger than the

Average age, 49. Average systolic blood pressure, 245.

Oedema: SBL, slight both legs; M. (hf), moderate (heart failure).

* NOTE.—The phenolsulphonaphthalein (P.S.P.) employed in these tests gives a low figure for the normal; 40 to 70 per cent. instead of the 60 to 90 per cent. given by that supplied by Hynson, Westcott and Dunning, on which most figures for the normal are based.

died the cause of death was cerebral hæmorrhage in three and in two cardiac failure, the longest interval between admission and death being seven months. In marked contrast to the other group, no death in uræmia has occurred. A further difference to which attention may be directed is the average systolic blood pressures. The average systolic blood pressure in Table I. is 220 mm. of mercury, in Table II. 245 mm.—that is, the patients showing the least disturbance of renal function have, on the average, the higher blood pressure. There are also minor differences to be noted in the frequency of small degrees of subcutaneous oedema and in the intensity of the albuminuria in the cases in Table I.

Significance of Grouping of Cases.

It would appear, then, that by our tests of renal function we have divided these cases of retinitis into

average age of those in Group 2? It is admitted that the number of cases is small, but the difference would seem too great to be accidental. It may be suggested that the greater renal damage in the younger group of individuals has occurred because their younger vessels are less prone to the degenerations which follow prolonged high blood pressure, and their hearts less likely to fail, so that there is time for profound renal destruction to occur; whereas in older patients death results from cardiac failure or vascular degeneration leading to cerebral hæmorrhage before the process in the kidney has had time to achieve its final stages. If this were so, and the cases in Group 1 represented the end stage of a single process, we should expect that

* The authors wish to emphasise that they are not dealing in this paper with acute nephritis, subacute and recurrent nephritis, or chronic nephritis with gross oedema. No example of any of these conditions occurred in this series.

in them the blood pressure would be highest. But such is not the case, for the average systolic pressure in this group of patients, with most marked renal destruction, is actually 25 mm. less than in the patients in the other group.

This observation is in agreement with the experience of Prof. H. M. Turnbull, Director of the Pathological Institute of the Hospital, who informs us that at post-mortem examination of subjects showing evidence of renal destruction and high blood pressure these two findings are usually, in degree, in inverse proportion to one another. That is, that cases showing the most profound degrees of renal destruction show usually only moderate degrees of cardiovascular hypertrophy, while in cases in which the cardiovascular hypertrophy is extreme the amount of renal destruction is usually, relatively, slight or moderate. Considering still the first possibility, that of a single process, a third suggestion might, perhaps, be offered—namely, the patients in Group 1 may represent those in whom some previous illness, scarlet fever, or an earlier acute nephritis, has left the kidney more susceptible to unfavourable influences, for example, the prolonged high blood pressure. This argument is more difficult to meet, evidence to support or confute it is difficult to obtain, and we are not in a position to deny the possibility. Personally we feel that the unsatisfactory nature of any of the above explanations forces us to consider the second possibility, that the two groups of cases represent the result of different pathological processes.

This we believe to be the case. We consider that the evidence we bring forward strongly supports the view that the patients in Group 1 are cases of primary renal disease with secondary high blood pressure, and that those in Group 2 are cases of high blood pressure with secondary renal damage. Such a difference in ætiology explains satisfactorily the differences in age, in degree of high blood pressure and its accompanying cardiovascular hypertrophy, in amount of renal damage, and in the mode of death. That the patient with hyperpiesis eventually develops, owing to degenerative changes occurring in his hypertrophied renal vessels, degenerative changes in the kidneys is generally recognised. It is, perhaps, not so generally realised that retinitis is also a frequent result.

We believe, then, that it is possible to separate, in this series of patients with retinitis, two very distinct underlying conditions—chronic interstitial nephritis, and (enlarging the use of Clifford Allbutt's term) hyperpiesis. We believe, also, that a similar differentiation can be made in most cases of high blood pressure. In chronic interstitial nephritis a patient in previous good health is taken, rather suddenly, seriously ill and is found even at the time of first examination to have gross deficiency of renal function. Progress is steadily downward, and death frequently occurs within a few months, and usually in uræmia. In hyperpiesis a longer period of ill-health usually precedes admission to hospital, the patients are generally older, and, on investigation, show relatively little disturbance of renal function. Life is generally more prolonged, and death, when it occurs, is usually from heart failure or cerebral hæmorrhage.

In this series of 19 cases of retinitis, nine, we believe, were patients with chronic interstitial nephritis, and 10 were patients with hyperpiesis. The number of cases is too small to justify the drawing of conclusions, but they suggest that hyperpiesis is a more common cause of retinitis than chronic interstitial nephritis. We believe hyperpiesis to be a much more common disease. Whether the cause of retinitis is the same in both these conditions and what is its nature we are quite unable to say. The only common factor in the two conditions would appear to be the high blood pressure.

Morbid Anatomy of the Conditions.

It is obvious that the study of this series of cases is very deficient in one important particular—namely, morbid anatomy. Unfortunately post-mortem examinations were obtained in only three of the 14 fatal cases: two of chronic nephritis (Nos. 2 and 4, Table I.),

and one of hyperpiesis (No. 6, Table II.). Prof. Turnbull kindly made a careful study of these three cases. He found in Cases 2 and 4 (chronic nephritis) "very great" destruction and fibrosis of the kidney, while in Case 6 (hyperpiesis) these changes were only "considerable." In Case 2 cardiovascular hypertrophy was "moderate" and intimal degeneration "slight"; in Cases 4 and 6 cardiovascular hypertrophy and intimal degeneration were "great." From the naked-eye examination at necropsy Prof. Turnbull considered the destruction of the kidneys in Case 6 to be ischæmic, in Cases 2 and 4 inflammatory; he failed, however, to find any special feature in the histology confirming this differentiation.

Shaw Dunn³ has recently appealed for a clearer classification of the pathology of chronic nephritis, and has attempted in particular to separate the "primarily contracted kidney" of chronic nephritis from the "arterio-sclerotic" resulting from high blood pressure. This study is the beginning of an attempt to attain by clinical investigation the same desirable result.

In conclusion, we should like to express our gratitude to Prof. Turnbull and to those physicians of the London Hospital who permitted us to investigate their cases.

A NOTE ON THE GERMICIDAL QUALITIES OF SODIUM DI-IODOSALICYLATE (DIOSAL).

By W. M. CROFTON, M.D. DUB.,

LECTURER IN SPECIAL PATHOLOGY, UNIVERSITY COLLEGE, DUBLIN;
PATHOLOGIST, DR. STEEVENS' HOSPITAL; CONSULTING
PHYSICIAN, ROYAL NATIONAL HOSPITAL FOR
CONSUMPTION, NEWCASTLE, CO. WICKLOW.

THIS compound was made for me by my colleague, Dr. J. Algar, D.Sc., first assistant to the professor of chemistry, University College, Dublin, who was associated with me in a research into germicidal drugs for the treatment of tuberculosis under the auspices of the Medical Research Committee. Dr. Algar supplies me with the acid, which is then dissolved in distilled water, to which is added the equivalent amount of decanormal sodium hydroxide. The solution used is 1 per cent.; it was found to have a very powerful germicidal action on *Staphylococcus aureus*, no growth occurring after treatment of a suspension containing 1000 million per c.cm. for ten minutes. The technique was as follows:—To 5 c.cm. of a 2 per cent. solution of diosal in a centrifuge tube was added 5 c.cm. of a suspension of *Staphylococcus aureus* (2000 million per c.cm.). The tube was then centrifuged for ten minutes, the supernatant fluid pipetted off, and the action of the diosal stopped by the addition of sterile distilled water and centrifuged again. The deposit of microbes was then inoculated on agar slopes. The experiment has been repeated many times, and no staphylococcus has ever been found capable of surviving 1 per cent. solution for ten minutes. All the catarrh-producing microbes, such as *Micrococcus catarrhalis* and streptococci, were found to be killed just as rapidly. The effect on the tubercle bacillus was very different, exposure of a concentration of bovine bacilli of 1000 million to the cubic centimetre for even 24 hours had no germicidal effect whatever; in fact, the effect was an improvement of growth—a very unexpected result. It was found in rabbits that a 1 per cent. solution produced no sign of irritation of veins or intravascular clotting when given intravenously. A rabbit weighing 5 lb. could take 1.5 c.cm. daily without obvious effect; 2 c.cm., however, made the rabbit ill, the animal passing very little urine.

Use of Diosal in Human Beings.

The drug produced no sign of intravital germicidal action on rabbits infected with bovine tubercle

³ J. S. Dunn; Brit. Med. Jour., 1922, ii., 1166.

bacilli either intravenously, subcutaneously, or by the inhalation of atomised droplets of water containing tubercle bacilli in suspension. Neither, however, did it appear to hasten their deaths, as might possibly have been expected by its increasing the growth of the bacillus in vitro. It has not been so far possible to reproduce the human pulmonary tuberculosis in rabbits—that is, a mixed infection with the tubercle bacillus and catarrh-producing microbes. It appeared to be legitimate, however, since the animal experiments were harmless, to try the product on human beings, especially on human beings so diseased that their lives were in imminent danger. On such a case

with antiseptics it was not feasible to take cultures from the stump. I made blood cultures and isolated streptococci in pure culture. I at once gave him 8 c.cm. of diosal pending the making of an antigen. He showed so much improvement I continued the diosal (see Chart 1) although the antigen was ready. About April 4th, 1922, the wound, which had so far had little discharge, began to produce pus and from this an autogenous antigen was made, with the result that his temperature became normal and remained so 48 hours after the first dose. The patient made an excellent recovery and has a perfectly sound stump.

CASE 2.—This was a case of moderately severe erysipelas of the head and face. Chart 2 speaks for itself. The autogenous antigen was given to prevent relapse.

CHART 1.

Temperature in a case of wound infection.

CHART 2.

Temperature in a case of erysipelas of head and face.

diosal was first tried. A young man under treatment for tuberculosis of both lungs with specific antigens and intravenous injections of iodoform in ether developed a double pneumonia after a visit from a friend who had a severe cold. His temperature ran up to 105° F. Diosal was given daily intravenously in 3 c.cm. doses, and as his temperature came down, as it did rapidly by lysis, the doses were reduced to 2 c.cm. and then 1 c.cm. daily. His immunisation was then resumed with a fresh catarrh antigen containing the new microbes. He made a remarkable recovery and lived for six years afterwards, doing light duty, and finally dying suddenly of "secondary" hæmorrhage.

I have used diosal in many similar cases with very remarkable results, and also in rheumatic conditions, both acute and chronic. I find it often very rapidly removes pain, and so I frequently employ it for this purpose while the specific antigens are being prepared. One has to be careful not to use it until the microbes are isolated. I had occasion to take another specimen of urine from a rheumatic case owing to the antigens which were being prepared for him having been contaminated; I found the urine sterile and had to stop the diosal for three or four days before I could get the infecting microbes, *S. aureus* and streptococci, to grow again. I hope diosal will have extensive usefulness in rheumatic fever as an adjuvant to immunisation.

While serving with the R.A.M.C. in Malta during the war I tried the drug in 3 to 5 c.cm. doses, given intravenously, in some severe cases of infected wounds and septic gangrene due to frost-bite. The drug appeared to act in a remarkable fashion, the temperatures falling rapidly. In two cases in which the drug did not appear to have this effect I found paratyphoid B bacilli in the blood. Diosal does not appear, therefore, to kill these microbes intravitaly.

Illustrative Cases.

The power of diosal as an intravital germicide was finally demonstrated by a desperate case of wound septicæmia.

CASE 1.—A male, aged 20 years, was admitted to Dr. Stevens' Hospital under Mr. W. S. Haughton on March 14th, 1921, with his right leg shattered by a gunshot wound. When I saw him on Dec. 24th he was blanched, severely dyspnoic, temperature 103.6° F., pulse 144. His leg had been amputated, and as it had been thoroughly treated

Diosal given intravenously does not appear to have much effect on local suppuration as in wounds, but I have reason to think it may prove very useful as a local antiseptic, a germicide that will kill microbes but not tissue cells.

A SUGGESTED ÆTIOLOGY OF BAKERS' DERMATITIS.¹

BY OSCAR DE JONG, M.B., CH.B. MANCH.,
D.P.H.,

HON. CLINICAL ASSISTANT, SKIN DEPARTMENT, ROYAL INFIRMARY,
LIVERPOOL.

FROM time to time cases are seen of more or less severe dermatitis on the hands and forearms in men and women engaged in some particular industry. Prosser White in his excellent book² has classified these forms of dermatitis; I here propose to deal only with dermatitis in bakers. This condition is of considerable importance to the individual, because of the distress of symptoms and loss of work, and to the employer and insurance companies on account of the question of compensation and the loss of a skilled workman. I have known cases where the baker has continued to follow his employment of mixing bread, despite the fact that his hands and arms were weeping, rather than lose his work and run the risk of failing to obtain compensation. The Ministry of Health has recently been investigating the condition, but I believe their findings have not yet been published.

Symptoms.

The symptoms of the disease are those of an eczema or dermatitis. The patient for a variable length of time follows his employment of mixing the dough until one day he feels a burning sensation on the ulnar and flexor surfaces of the forearms and the backs of the hands, associated with some degree of pruritus. This is followed by a small papular eruption, which becomes vesicular and finally breaks down and weeps freely and is associated with very marked itching which becomes worse when the arms are heated. The areas,

¹ A paper read before Liverpool Medical Institution.

² R. Prosser White: Occupational Affections of the Skin. London: H. K. Lewis. 1915.

which vary considerably in size, become secondarily infected, usually by a form of staphylococcus, and scattered deep-seated pustules are then found. These symptoms continue as long as the patient remains at his work.

Bakers' Materials.

There have been various suggestions made as to the aetiology of the disease, one being the presence of a parasite in the flour, giving to the disease the name of "bakers' itch." Latterly it has been suggested that the patient is sensitised by the flour protein. Again, it has been thought that the presence of chemicals, calcium persulphate and nitrites, so-called "improvers," in the flour, have been responsible for the condition, or that the yeast or some other fungus sets up the dermatitis. Any one of the above might have been the important factor in producing the condition, and in this investigation I found it necessary to examine each of them.

Flour.—With regard to the flour, I visited two of the largest flour mills in the country. In each mill I found a male welfare supervisor, who assured me that cases of skin trouble on the hands and arms of workers were unknown. I also spoke with the workmen, and obtained the same reply. The men were covered from head to foot with flour dust day after day, so I felt justified in concluding that the flour itself was not the direct cause, and that there was no question of direct sensitisation by the flour protein. I obtained samples of the flour from the bakehouses in which the patients were working; and these I submitted to Prof. W. H. Roberts, of Liverpool, who very kindly investigated them for me, reporting that he found no chemicals, acari, or fungi present.

Yeast.—With regard to the yeast, inquiries made at the distillery revealed no instances of dermatitis or eczema in the men engaged in manufacturing or packing the yeast. Incidentally, I may mention that a manager of a distillery had heard that yeast was good for boils and also acted as a preventive; he was not suffering from furunculosis at the time, but he thought that having the yeast he might as well take some. After taking it for some weeks he commenced with a carbuncle which took three months to heal, so he informed me.

Bakers' Methods.

I next directed my attention to the conditions and methods under which the bread was made. It will be found on inquiry from a patient that he is employed in a bakehouse where the dough is mixed by hand. I have not found bakers' dermatitis in men employed in bakehouses where the bread is mixed by machinery. The method of mixing is as follows: Two sacks of flour, weighing about 280 lb., are placed in a trough; into another trough are placed 9 lb. of salt and 24 gallons of water; 4½ lb. of yeast are mixed with a gallon of water in a bucket and added to the trough containing the salt and water. The mixture of salt, yeast, and water is then mixed by use of the hands and arms and aerated by raising the mixture with a can and allowing it to fall from a height into the trough. A quantity of the salt-yeast mixture is added from time to time to the flour in the other trough and this is kneaded with the hands and forearms. This process is continued until the salt-yeast mixture is used up, and the dough mixed and ready for weighing and baking.

This routine is followed by the baker day after day and week after week. He is using a solution of 9 lb. salt to 25 gallons of water—that is, approximately a 3·6 per cent. solution, or about 17 gr. to the ounce. The temperature of the water used is between 70° and 80° F., and the temperature of the bakehouse is about 110° to 120° F. From time to time the baker has to leave his mixing of the salt and yeast mixture to attend to his oven, and my patients tell me that the salt crystallises on their hands and arms in the interval. These crystals are worked into the skin in the process of kneading.

An "Idiosyncrasy" for Salt.

It seems to me, therefore, that the salt may justifiably be regarded as the direct cause of the condition,

but the patient must display an idiosyncrasy, if I may be pardoned for using the word, for the salt, as the condition is not found in all bakers.

It is interesting to note that dermatitis occurs in people other than bakers who are habitually engaged in the handling of salt—for example, herring salters and packers, and rock-salt workers. The important fact remains that a man suffering can be cured under simple treatment on being removed from his work if there are no secondary symptoms, but that on his return to work he will relapse. I think that he is entitled to compensation, as the Act states that any powder or liquid used in the process of his work entitles a man to compensation if the powder or liquid can be shown responsible for the condition. This is an important point for the insurance companies because it means that any insured baker suffering from dermatitis will, as long as he continues to work, be off for long periods and draw compensation, whereas in some other employment he would be able to work without this disadvantage.

I do not in this short note propose to discuss treatment, but I think that a measure of prophylaxis would be found in the provision of a rose spray of running fresh water under which the man might rinse his arms from time to time, especially before going near the oven, and at intervals during the kneading.

THE EFFECT OF DETOXICATED VACCINES ON THE PERSISTENCE OF THE DIPHTHERIA BACILLUS.

BY W. TYRRELL BENSON, M.D. EDIN.,

B.Sc. ST. AND., D.P.H.,

LATE BACTERIOLOGIST AND SENIOR ASSISTANT, CITY HOSPITAL,
EDINBURGH.

AT various times many remedies have been put forward to effect the cure of the diphtheria carrier. The result up to the present has not been satisfactory, although there appears to be a distinct hope of success in surgical methods of treatment, particularly in the case of faucial carriers. The administration of vaccines has met with varying results in the hands of different investigators. The vaccine used has been in some cases an autogenous, in others a stock, and more recently a detoxicated Klebs-Löffler preparation. The dosage administered has varied from 10 millions or less up to, in the case of the detoxicated vaccine, the single huge dose of 350,000 million organisms. The method of administration and the intervals between doses differ also. We have a choice of subcutaneous, intramuscular, or intravenous routes, and any interval of time between doses that we please, though injections repeated at weekly or three-day intervals seem to be most favoured.

In the administration of any vaccine the dosage is most important. It should always aim at being the largest possible, consistent with the absence of any marked general reaction. In the use of ordinary specific vaccines the dosage is very definitely limited, owing to the production of unpleasant constitutional symptoms. This is presumably due to their high toxin content. With these toxic vaccines the largest possible dose is usually small and inadequate, and the amount of antibody formation is correspondingly minute. In the case of detoxicated vaccines it has been asserted that we have a product from which the toxic factor has been removed, and yet the immunising property retained.

Fraser and Duncan,¹ using detoxicated Klebs-Löffler vaccine, met with some considerable measure of success in the treatment of chronic diphtheria carriers. F. M. Wood² claims that by employing his vaccine antitoxin treatment of diphtheria the

¹ Fraser, A. R., and Duncan, A. G. B.: THE LANCET, 1920, II., 994.

² Wood, F. M.: New York Med. Jour., Jan. 10th, 1920.

production of toxin is stopped from the time that the vaccine is administered; the antitoxin neutralises the toxin already formed; in carriers the bacilli are destroyed. He states that in cases of diphtheria the Klebs-Löffler bacillus disappears from the throat within ten days, thus shortening the quarantine period.

If such results were attainable by using moderate doses of an ordinary diphtheria vaccine it appeared to me that a detoxicated preparation used on the same principle would perhaps be even more effective. This I proceeded to test.

Dosage.—Reactions.

The question of dosage had now to be decided. J. L. Brownlie,³ using an ordinary diphtheria vaccine, successfully cleared up some 50 convalescent cases, his dosage varying from a total of 10 to 200 million bacilli. Wood administered three doses of 300 to 500 million bacilli at three-day intervals. Fraser and Duncan, using detoxicated Klebs-Löffler vaccine, obtained negative cultures in two chronic carriers after a total dosage of 8900 million and 20,700 million bacilli respectively.

The routine dosage of detoxicated Klebs-Löffler vaccine I adopted was an initial dose of 2000 million bacilli, followed at three-day intervals by two more doses of 4000 and 8000 million bacilli respectively, making in all a total of 14,000 million organisms. This dosage was adhered to irrespective of age or severity of disease. The initial dose was given on the day of admission in addition to the usual treatment by antitoxin. All the injections were given subcutaneously. Vaccine-treated cases were alternated with control cases, which did not receive vaccine, until some 60 of the latter had been obtained, after which every case was treated with vaccine. No selection was exercised as to which case was to receive vaccine and which was not. They were strictly alternated. A certain percentage of cases sent in to the hospital notified as diphtheria were found to be follicular tonsillitis, Vincent's angina, &c., and these had to be excluded from the series.

The local reaction was very slight, and caused no discomfort beyond some slight tenderness to touch. In all, some 500 doses of vaccine were injected subcutaneously, ranging from 2000 million to 20,000 million organisms, and in no case did constitutional symptoms arise.

Method of Estimating Total Persistence of Bacilli in Convalescents.

Cultures from fauces and nose were taken at weekly intervals in both series of cases until a negative culture was obtained. Cultures were then taken on alternate days until three consecutive negatives were obtained. If a positive culture followed a negative result, as often happened, the culture-time reverted back to weekly intervals until another negative was obtained, when cultures at two-day intervals were again started. If three consecutive negative cultures were obtained early in convalescence, some considerable time before the patient was fit to be discharged, then cultures were again examined in the week previous to discharge. Many cases thus had five, and some even seven, consecutive negative cultures as evidence of their freedom from diphtheria bacilli. The day half-way between the date of the last positive culture and the first of three or more consecutive negative examinations was taken as the day on which the patient last harboured the diphtheria bacillus. The results thus obtained gave the number of days the diphtheria bacillus persisted in the throat or nose of the patient after admission to hospital. In working out the total length of persistence of bacilli, I have calculated the number of days from the date of the first symptom to the final disappearance of bacilli, as judged by at least three consecutive negative cultures examined on alternate days.

³ Brownlie, J. L.: THE LANCET, 1920, i., 706.

1. Effect of Vaccine on Time of Disappearance of Bacilli.

Does the diphtheria bacillus disappear at an earlier date from the throat and nose of the vaccine treated case than from that of the non-vaccine treated case? In a series of 207 clinical and bacteriological cases of diphtheria, 146 were treated with detoxicated Klebs-Löffler vaccine as described above, whilst 61 were control cases. Both series of cases were adequately dosed with antitoxin, according to the severity of the disease. (Table I.)

TABLE I.

A = Non-vaccine cases. B = Vaccine cases.

	Day of disease on admission to hospital.												
	1st	2nd	3rd	4th	5th	6th	7th	8th	9th	10th	11th	12th	13th
A ..	3	10	16	16	7	3	1	3	0	1	0	0	1
B ..	3	32	34	40	18	7	4	4	1	1	0	1	0

The mean number of days of illness previous to admission to hospital in 61 non-vaccine cases was 3.96 days, and in 145 vaccine cases 3.77 days.

Dividing the cases up into those admitted up to, and on the fourth day of illness, and secondly, those admitted later, we find the result given in Table II.

TABLE II.

Cases admitted—	Non-vaccine cases.	Vaccine cases.
First to fourth day of illness inclusive	Per cent. 73.77	Per cent. 75.35
Fifth day of illness and later	26.23	24.65

The figures in Table II. show that treatment was started on approximately the same day of illness in both series of cases.

With regard to the severity of the cases in the two groups as judged from the amount of antitoxin administered, we find the result given in Table III.

TABLE III.

Cases receiving—	Non-vaccine cases.	Vaccine cases.
6000 units of antitoxin or less	Per cent. 70.00	Per cent. 76.72
More than 6000 units of antitoxin ..	30.00	23.28

The figures in Table III. show a slightly higher proportion of severe cases in the non-vaccine group than in the vaccine group.

The rate of disappearance of diphtheria bacilli is shown in Table IV.

TABLE IV.

Mean persistence of diphtheria bacilli in throat or nose after disappearance of membrane.

In 55 non-vaccine cases 16.51 days.

In 144 vaccine cases 14.08 "

Mean persistence of membrane.

In 55 non-vaccine cases 6.47 days.

In 144 vaccine cases 6.53 "

The duration of membrane is calculated from the day of the first symptom to its final disappearance.

Mean persistence of diphtheria bacilli in throat or nose from first symptom to final disappearance.

In 55 non-vaccine cases 22.98 days.

In 144 vaccine cases 20.61 "

Mean persistence of diphtheria bacilli in cases of nasal diphtheria.

In 4 non-vaccine cases 36 days.

In 13 vaccine cases 39 "

* One case still harboured diphtheria bacilli 120 days after admission to hospital.

Table V. shows percentage rate of disappearance in successive seven-day periods.

TABLE V.

Days from onset of disease.	Non-vaccine cases.		Vaccine cases.	
	Number of cases which became negative in each week.	Cumulative percentage.	Number of cases which became negative in each week.	Cumulative percentage.

43-49	1	94	6	97
50-56	3	100	0	97
57-63	—	—	3*	99

* One case with diphtheria bacilli still in nose 120 days after first symptom.

2. Effect of Vaccine on Persistence of Bacilli in the Convalescent.

Does the administration of vaccine prevent the prolonged persistence of diphtheria bacilli in the throat and nose of the convalescent case? From Table V. we see that three cases harboured bacilli up to the eighth week. Of these, two were faucial

carriers and one nasal. One case treated with three doses of vaccine, a faucial and nasal diphtheria on admission, still harboured virulent diphtheria organisms in the nose 120 days after admission to hospital.

Conclusions.

The administration of detoxicated Klebs-Löffler vaccine in the particular manner and dosage I adopted (a) has no appreciable effect in hastening the disappearance of the diphtheria bacillus from the throat or nose of the diphtheria convalescent, and (b) does not prevent those cases of prolonged persistence to which, after an arbitrary period of three months, we apply the term "chronic carrier."

I might mention that, so far as could be observed, and taking into account the small number of cases dealt with, the administration of vaccine appeared to have no influence on the clinical course of the case.

It is with pleasure I express my thanks to Dr. C. B. Ker, medical superintendent, City Hospital, Edinburgh, for the facilities he placed at my disposal, and his unfailing interest; also to Messrs. Genatosan, Ltd., who very kindly kept me supplied with detoxicated Klebs-Löffler vaccine.

Medical Societies.

OPHTHALMOLOGICAL SOCIETY: ANNUAL CONGRESS.

THE Annual Congress of the Ophthalmological Society of the United Kingdom was held on April 26th, 27th, and 28th at the House of the Royal Society of Medicine and (for the clinical meeting) at the London Hospital. The chair was occupied by the President for the year, Dr. A. MAITLAND RAMSAY (Glasgow).

Opening Address.

The PRESIDENT delivered his inaugural address, choosing as his subject the debt which general medicine owes to ophthalmology. He said it was easier for most men to trust in authority than to exercise independent judgment, but the trend of modern progress was to appeal less and less to authority. Specialism was the natural sequel of increase in knowledge, and it should be symbolic of the highest form of efficiency. The tissues of the eye were so delicate, its structure so complicated, its diseases so numerous and so frequently followed by disastrous results that it was no matter for wonderment that oculists had existed from time immemorial, though in quite early days their claim to practise the speciality were very poor, as they had not acquired the general principles of medicine and surgery. The specialist in medicine must combine the diagnostic skill of the physician with the dexterity of the surgeon, and add that special knowledge which gave him power to reach further. It should be the aim of every specialist, by reading and frequent visits to a general hospital, to keep in touch with medicine, at least along its most important lines of advance. But there should be no hurry, as that might lead to specialisation too early, to the cultivation of one department to the exclusion of others. The study of ophthalmology, he contended, constituted the best discipline in exact observation in the whole medical curriculum: it was, indeed, an education in itself, for absolute precision was of the first importance. It was a great aid, too, to a methodical investigation of diseases of the nervous system. Such a purely ocular condition as optic atrophy, ocular palsy, or loss of the pupillary light reflex might lead to the diagnosis of tabes dorsalis. One patient he saw had been blind from optic atrophy 20 years before the onset of the more widespread manifestations of disease of the spinal cord. Likewise the study of the eyes might give

decisive evidence of disease of brain or kidneys. Homonymous hemianopsia might be the only proof remaining of a past cerebral hæmorrhage, and its recognition where paresis had been slight and transient would prevent the physician falling into error, either in regard to diagnosis or prognosis. On account of the transparency of its structures, the eye had always been the hunting-ground of the pathologist; pathological changes usually hidden from view could be seen and watched in the eye from day to day.

For some years he had been working with Sir James Mackenzie, to whose teaching he owed a great deal of inspiration. He had been struck by the similarity of action of ciliary muscle and cardiac muscle. In both, the limits of muscular capacity must be respected and the amount of work to be done should be adjusted accordingly. Of all the unstriped muscles in the body, it was only the ciliary muscle and the cardiac muscle which could be forced by the will to continue working long after Nature had called for rest; the former of these was active all through the waking hours, and the latter was incessant. The reserve power of both became less as age advanced. Loss of power in the eye could be measured and glasses prescribed accordingly; but in the case of the heart which was using up its reserve, all that could be done was to limit its work in accordance with its capacity. The power of accommodation could be regarded as a fair index to the general health. In emmetropes who were robust, the need for spectacles could be delayed beyond the usual age, just as the heart of some elderly people permitted them to play strenuous games; but in them the rapid onset of presbyopia was always a sign of failing health, and that the person was not likely to live much longer. Adults often complained of their eyes after influenza, and children often suffered from their eyes for the first time after measles or scarlet fever; in fact, sight was quickly affected in all disorders of the body. Inability to use the eyes for close work on account of excessive pain, with hyperalgesia of the skin of the scalp, were symptoms in every way comparable with those present in angina pectoris. The acute symptoms might not be manifest until some hours after the causal effort.

In conclusion, he said the gain to scientific medicine would indeed be great when the ophthalmologist coöperated closely with the family doctor and kept himself informed of the subsequent medical history of patients who had consulted him on account of failing sight, and when, on the other hand, the general practitioner brought his medical knowledge, experience, and common sense to bear on all the ophthalmological problems with which he might be confronted in his work.

Mr. E. TREACHER COLLINS read a paper on
The Aetiology of Angeoid Streaks in the Fundus Oculi.

He said a comparison of the arrangement of these streaks in the different recorded cases showed that they presented certain common characteristics, which could only be accounted for by there being some anatomical factor upon which their distribution depended. Their arrangement, he showed, corresponded closely to that of the circle of Zinn of the short posterior ciliary arteries around the optic disc, and of the main branches proceeding from it. Ophthalmoscopic observations by several different writers showed the undoubted hæmorrhagic origin of these streaks. The hæmorrhages from which they had been seen to arise were never situated in front of the retinal vessels, nor were they flame-shaped like retinal hæmorrhages, but presented the characteristics of subchoroidal or interchoroidal hæmorrhages. Blood effused between the choroid and sclerotic, due to its slow absorption, would, like blood stagnant in other parts of the body, tend to give rise to insoluble crystals of hæmatoidin and hæmosiderin. These, if deposited in the perivascular spaces around the branches of the short ciliary arteries, would account for their pigmented appearance when viewed ophthalmoscopically.

The other fundus changes commonly met with in association with angeoid streaks, such as haze or pigmentation of the retina, various degrees of atrophy of the choroid, &c., were also, he said, adequately explained as the outcome of subchoroidal hæmorrhage. There was not yet sufficient evidence as to why patients suffering from this affection should have choroidal hæmorrhages.

Consecutive Cases of Cataract Extraction by Barraquer's Method.

Mr. R. AFFLECK GREEVES and Mr. R. FOSTER MOORE read independent papers on this subject.

Mr. Greeves's contribution was based on 49 patients from whom he removed, or attempted to remove, the lenses by Barraquer's method. In two cases he removed the lens from each eye, making the total number of lenses 51. The cases he divided into three groups. In Group 1 (31 cases) the lens was successfully extracted in its capsule. In Group 2 (7 cases) the capsule broke during the operation, but he was able to extract the greater part of the lens substance with the suction instrument, the capsule left behind being subsequently needled in the usual way. In the third group (13 cases) the lens could not be delivered by the suction instrument, and the use of the scoop was necessary. The cases in the second group mostly ran the same course as those after extraction by the old method, and in each case the secondary cataract was needled. In one, needling was a failure, and he proposed to perform iridotomy. In all the 13 cases a scoop was used. In the majority very little vitreous was lost, and on the whole he did not regard the visual results as unsatisfactory. The smallness of the vitreous loss was probably due to the lens being already dislocated forwards. In one case the cataract was hyper-mature and the zonule weak. If a complete iridectomy had been done, the corner of the coloboma might become caught in the edge of the cup and prevent extraction. Another possible reason was the giving way of the lens capsule after the lens was dislocated. A further cause for failure was an unknown variability in the negative pressure obtainable due to the changes in strength of the electrical current which actuated the motor. He entered into the technique of the operation, and gave particulars of each of the 51 lenses treated. In conclusion he said his view was that the result of a successful intracapsular extraction by this method left nothing to be desired. The pupil was black and free of membrane, the media were clear, the visual acuity was excellent, and there was no undue amount of astigmatism. On the other hand, however, the method had shown itself to be less certain in its results than extraction without the capsule.

Mr. Foster Moore's paper was based on 38 cases; he had excluded 6 in which he operated with an improvised method of producing the vacuum before the Barraquer apparatus was available. Concurrently with doing this operation at Moorfields, he had been, at St. Bartholomew's Hospital and in private, carrying out the extra-capsular method, and this enabled him to judge the better of the respective merits of the procedures. He described a modification of Barraquer's instrument which he had been using; this enabled more delicate manipulation to be carried out, and had no valve which could get out of order. His chief difficulty had arisen from the separation of the cup from the lens when traction had been applied, so that in some cases the instrument had to be re-applied a number of times. Sometimes rupture of the capsule had ensued, sometimes recourse had to be had to the cystotome or scoop. He was sure some of the difficulties had been due to defective suction; in the earlier cases it was not appreciated how poor the suction was. In the latest Barraquer instrument a manometer was incorporated—a great gain. Of the 38 cases, 22 could be said to have had a quite successful result, the lens being removed entire in its capsule, and there were no difficulties or complications at the time. In 5 others the lens was removed in its capsule, but there was some loss of vitreous. Thus there were 11 cases in which he failed to remove the lens with the instrument, and other means of doing so had to be resorted to. In 7 cases the lens was expressed after either rupture of the capsule by the instrument, or after cystotomy; and in 4 cases the scoop had to be resorted to. In 9 cases in the series there was loss of vitreous. In one, suppurative occurred and evisceration was performed. In every other case some useful vision at least resulted.

He proceeded to discuss the advantages and disadvantages of the method. Among the advantages were that the whole capsule was removed with the lens, tags of it could not become incarcerated in the incision, and, further, no secondary needling operation was necessary. An important advantage, also, was absence of post-operative iritis. And it was gratifying to see a uniform black pupil after the operation. The outstanding disadvantage of the method was the frequency of vitreous loss and its consequences. When such loss occurred he did not doubt that the prognosis, both immediate and remote, was worse than when there was no such loss. In 23·7 per cent. of his cases there was loss of vitreous. And a very important result was that the welling of the vitreous into the wound carried the pillars of the iris into the incision, and a deliberate attempt to replace them resulted in further loss. And should any secondary operation be needed in the first day or two, the risk of vitreous loss again became important. The danger, however, was much minimised by paralysing the orbicularis with novocaine. In Barraquer's method the lens was drawn out of the eye, not expressed from it; therefore a slight negative pressure was developed within the globe, so that the vitreous tended to suck back rather than to follow the lens, and this might render loss of vitreous more frequent than would otherwise be the case. And in many cases there was need for a complete iridectomy. Altogether, he considered that the operation had in it a considerable element of danger, especially in the matter of vitreous loss, so that for general use it was inferior to the older method. But for immature cataracts and sclerosed lenses the Barraquer method had distinct advantages of its own.

Mr. MALCOLM HEPBURN commended the courage and enterprise of the readers of these two papers, but remarked that the success of this operation depended largely on a machine rather than upon the surgeon's personal skill. Therefore it was not surprising that some of the unsatisfactory results were ascribed to deficiency in the electric current. A further objection was that the instrument had to be held so tightly that it interfered with delicate movements. He did not think the Barraquer method was likely to replace the older operation.

Mr. HARRISON BUTLER emphasised the value of paralysis of the orbicularis muscle by novocaine. Since he saw Mr. Foster Moore do this, he had himself carried it out in every case, as a routine. It gave the surgeon a sense of security and was a comfort to the patient.

Mr. J. H. FISHER discussed the mode of action of the original Barraquer instrument and of the recent modifications.

Mr. LESLIE PATON asked to what extent the operators by this method depended upon the rocking movement of the lens so as to secure the abolition of the vacuum between the back of the lens and the hyaloid cup, so as to diminish the risk of vitreous prolapse.

Colonel H. SMITH, I.M.S., said he thought secondary operations for cataract should be deferred for ten days. With regard to the capsule holding back the vitreous, the hyaloid was not completely independent of the capsule of the lens, as Prof. Anderson Stewart showed in 1894. The iris tended to be pushed more forward in intracapsular extraction than after the ordinary operation; and in the former, too, there was greater liability to prolapse of iris. If all else was as it should be, loss of vitreous, even to the extent of one-third, did not militate against the eye lasting as well as an ordinary eye. He was inclined to think that in these cases vitreous was renewed, but he could not be sure on the point. A drawn-up pupil was a too frequent sequel of these operations. He also emphasised the need of thorough control of the orbicularis during the operation. For this he preferred the ordinary squint hook to the injection of novocaine. Any procedure or instrument which was inelastic was liable to fail. He congratulated Mr. Neame and Mr. Foster Moore on their adventure into this field.

Lieut.-Colonel H. KIRKPATRICK, I.M.S., spoke of the efficacy of Colonel Smith's control of the orbicularis in doing the operation for cataract. He considered that loss of vitreous must be looked upon as a disaster in the operation, and anything which diminished the loss of vitreous must be regarded as an advantage.

Mr. GREEVES and Mr. FOSTER MOORE replied.

(To be concluded.)

SOCIETY OF MEDICAL OFFICERS OF HEALTH.

A MEETING of this Society was held at 1, Upper Montague-street, London, W.C., on April 20th, Dr. T. EUSTACE HILL, the President, being in the chair. On behalf of the Metropolitan branch Sir WILLIAM HAMER presented to the Society a portrait of Dr. W. J. Howarth, who being a member of that branch was president of the Society last session. Dr. EUSTACE HILL, in accepting the gift for the Society, eulogised the great services which Dr. Howarth had rendered during his year of office.

Dr. A. H. BYGOTT (county M.O., West Suffolk) then read a paper entitled

Death Certification, More Especially as it Affects the Office of Coroner.

He proposed that the work done by the coroner should be divided, the medical part being done through medical officers of health and the legal part by the legal department of counties and county boroughs working with the police. A medical study of each individual death was likely to suggest preventive measures, and public health authorities could no longer afford to acquiesce in the coroner's office being ad hoc. That office dated from the time of the Saxon kings, and much of the law dealing with it belonged to the thirteenth century and was not well suited to the conditions of modern life. In England and Wales there were about 330 coroners with salaries varying from under £20 per annum to over £1000 and amounting to £77,477 in all, not including certain other expenses. In 1920 53,714 deaths (11.5 per cent.) were referred to coroners, in respect of which 31,486

inquests were held (the others being investigated without inquests) and 12,310 post-mortem examinations were made. There were 192 verdicts of murder, 89 of manslaughter, 6 of justifiable homicide, 137 of felo-de-se, 3236 of suicide, 23 of deaths from neglect of others, 88 from want and exposure, 13,741 from misadventure, and 11,748 from natural causes. There were also 1733 open verdicts. The speaker further pointed out that the proportion of reported cases dealt with without inquest and also the proportion in which post-mortem examinations were made varied very greatly with different coroners. In country districts the numbers of post-mortems were usually low. Under the present system the number of open verdicts was high. The number of murder cases from poisoning was small, and judging from some recent cases Dr. Bygott suggested that a better system of inquiry would reveal more of these. Deaths from accidents were high and many were preventable, which he claimed was an unanswerable argument for improving the system and associating it with other health activities.

The Medical Officer of Health as Coroner.

The Select Committee on Registration and Certification (1893) recommended that all medical death certificates, for which a fee of 2s. 6d. should be paid, should be sent to the Registrar by post as confidential documents, that all uncertified deaths should be reported to the coroner, and that in every sanitary area the M.O.H. should be appointed as public certifier to investigate deaths and report to the coroner if the circumstances were not satisfactory. The Departmental Committee on Coroners' Law (1909) reported that "the present law of death certification offers every opportunity for premature burial and every facility for the concealment of crime." In 1913 Dr. W. A. Brend read a paper to the Medico-Legal Society in which he suggested that a private inquiry by a medical coroner should replace the present system and that the office should be definitely a medical one instead of legal. He did not, however, deal with the interest which public health authorities had in the question. Dr. Bygott claimed that experience of the past eight years showed that inquests without juries were quite practicable in this country. The value of the jury had disappeared since medical evidence had taken the place of inspection of wounds and the like by members of the public. The compass which guided the M.O.H. was his vital statistics, especially death returns. He was a man of standing in his profession not engaged in private practice either as a doctor or solicitor, and was capable of organising the work of ascertaining the cause of death. Dr. Bygott therefore suggested that the office of coroner as it exists should be abolished and that inquiries into the cause of death should be dealt with by the M.O.H. of counties and county boroughs, any legal action required being undertaken through the clerk of the council assisted by the police.

Anomalies of the Present System.

The present system was both costly and inefficient. The procedure of inquests was mediæval, and caused waste of time and undue publicity to the affairs of a family in great distress. There was no official regulation of procedure, the laws of evidence were disregarded, and the investigation could only deal with a body, which might be in a different district from that in which the crime (if any) was committed. If the body was not found, no inquest could be held. The existence of franchise coroners was an anomaly, their salaries and expenses being paid by county councils, while they were nominated by private individuals or corporations. While most coroners were either solicitors or medical practitioners some were neither, and there was no statutory qualification except the holding of lands in fee. Except in a limited number of cases there was no statutory duty to report to the coroner, though registrars were instructed to do so whenever they were aware of a death not accompanied by a medical certificate. The coroner's officer on whose

report the coroner acted was not always a member of the police force and was sometimes a very unsuitable person. The coroner had no power to order and pay for a post-mortem examination unless an inquest were held, though this would often make the inquest unnecessary. He had no medical department at his disposal in cases involving highly complicated scientific investigation, though the Home Office might give help in certain cases. A doctor could not obtain scientific help in cases in which he suspected poisoning, and if his fears were groundless a public inquiry might place him in a very unenviable position. The present rule of viewing the body was objectionable. It was of no assistance, and it often necessitated the inquest being opened before the scientific inquiries were complete. Many of the post-mortem examinations ordered by coroners were carried out in very unsuitable premises, by inexperienced men working without proper facilities, and the mortuary attendants were often of an undesirable character. Much better work might be done with proper organisation, capable of rendering important service to legal and curative medicine. This should be one of the first cares of the Ministry of Health. Moreover, friends object to post-mortems and they had a right to expect them to be done under decent conditions. Another anomaly referred to was the fact that in cases involving criminal proceedings the case was tried by both the coroner's and the magistrate's court before committal to the assizes, and that the decisions of the two courts sometimes differed.

Dr. Bygott criticised the Bill now before the House of Commons, entitled "Coroners' Law and Death Certification Amendment." He suggested that the expense of the proposed reforms was greater than the improvements would justify, and that the proposals were inferior to those which he was submitting. Some of them he suggested were objectionable, and there were many existing anomalies with which the Bill failed to deal.

Discussion.

The PRESIDENT remarked that it was now 30 years since the Select Committee had reported on many of the very points which Dr. Bygott had raised. With regard to the proposal that the M.O.H. should be required to inquire into deaths, this could only be done by the appointment of suitable persons on his staff. His time was too fully occupied for him to do the work personally. He spoke of unqualified medical practice, which Dr. Bygott had said would be discouraged if full medical inquiries were made into every death, and remarked that in one district in Durham County over 20 per cent. of deaths were uncertified because of the prevalence of such practice. Some years ago, on instruction from the Local Government Board, the coroner held inquiries into every uncertified death, and this had a very good effect in restricting unqualified practice. The instruction was afterwards withdrawn. That criminal negligence and crime often went undetected was clear from the cases in which the Public Prosecutor obtained convictions when these circumstances were not revealed as the result of the coroner's inquest.

Dr. F. E. FREMANTLE, M.P., observed that Dr. Bygott's proposals raised questions of privilege and office which would necessarily cause strenuous opposition, and that the attitude of the legal profession, extremely powerful as it was, might be hostile. If the matter could be ventilated and threshed out in the Medico-Legal Society this might induce the lawyers to look upon it more favourably. It fell within the province of the Home Secretary and his legal advisers. In regard to the proposals in connexion with the M.O.H., Dr. Fremantle submitted that it would only be possible for him to deal with the matter administratively. The present Bill was not regarded as a solution of the problem, but it broke the ground and prepared the way for further action in the future. Much work on the subject would be required and it would be necessary to show that the present system actually caused harm and

loss to the State. That the office of coroner was anomalous was not important; the important question was that of efficiency. In considering reforms on the medical side the importance of the legal side must not be lost sight of.

Dr. C. PORTER (M.O.H., St. Marylebone) felt that as compared with Dr. Bygott's proposals there was much more chance for the other reform that had been a good deal canvassed—viz., that the M.O.H. should be appointed as registrar of deaths instead of a layman. Such a reform as this might make the further proposals in regard to the office of coroner more practicable later. He did not think that the proposal to divide the work of the coroner between two different officials, medical and legal, would meet with much favour. The removal of established officers was always a difficult task.

Reply.

Dr. BYGOTT said that he had in mind in his proposals that the M.O.H. would not carry out the details of the office personally, but through his staff. He had purposely refrained from discussing the question of the M.O.H. acting as registrar, as not being germane to his subject. It would be much easier to make this change as to registration in the towns than in many rural areas.

LIVERPOOL MEDICAL INSTITUTION.

A MEETING was held on April 12th, Prof. J. HILL ABRAM, the President, being in the chair.

Exhibition of Cases and Specimens.

Dr. J. R. LOGAN read a note on Unusual Mineral Deposit in Soft Tissues of the Hands, and showed X ray photographs. The patient was a female, aged 60, suffering from a mild degree of Raynaud's disease. The hands and feet were always cold, the former often of dusky blue colour; dilated veins were visible on face, ears, and tongue. The mineral deposit was not found in the toes. There were many nodules on the sides and palmar surfaces of fingers and thumbs, in the subcutaneous tissue, not specially near the joints. Analysis showed that there was no trace of uric acid, and that the substance giving the dense shadows was phosphate and carbonate of lime.

MR. ARTHUR EVANS read a note on a case of Fracture-dislocation of the Fourth Cervical Vertebra. The patient, having fallen from a motor-lorry, was admitted into the Southport Infirmary under the care of Dr. Reinhardt Anderson. The injury was followed by a definite paresis of both upper and lower limbs with sensory phenomena indicating a lesion of the fifth cervical segment of the cord. There was definite tenderness over the region of the fourth cervical spine. A radiograph showed a well-marked fracture-dislocation forward of the fourth cervical vertebra upon the fifth below. Expectant treatment was carried out, but the patient's condition became stationary in a short period of time. Laminectomy therefore was performed six weeks from the date of the accident, the spines and laminae of the third, fourth, and fifth cervical vertebra being removed. The cord, at the level of the dislocation, was found to be grooved and indented in its entire circumference by the laminae of the fractured vertebra behind and in front by the "angulation" produced by the body of the vertebra below the dislocation. The patient made a steady and rapid recovery. Twelve months from the date of his injury he was able to resume his ordinary employment as a mechanic in a well-known motor factory, an occupation requiring not only considerable muscular strength, but unusual deftness of hands and arms.

Prof. R. J. M. BUCHANAN introduced a discussion on

Non-obstructive Jaundice.

He considered that distinction should be made between jaundice without gross obstructive lesion

and jaundice from other causes. He held that the condition was always in the last event due to obstruction to the biliary secretion, even in cases where the cause was an inflammatory condition on the liver. Prof. Buchanan reviewed the differential diagnosis and the value of the Cammidge reaction and of the chemical test introduced by Van den Bergh. He discussed the difficulty that arises in the diagnosis between jaundice that was purely hæmolytic in origin and forms in which there was some functional derangement in the hepatic cells.

Dr. E. CRONIN LOWE said that jaundice was a symptom arising from derangement of hepatic function from many causes. Among the most common was infection of intestinal origin, the infection proceeding by way of the portal circulation. Mild jaundice could also be demonstrated in the early stages of many infections which were not portal. He considered that Van den Bergh's test should prove of great assistance in the diagnosis between gross obstruction and catarrhal cellular hepatitis. He had not found absence of post-prandial leucocytosis reliable as an indication of hepatic deficiency. All cases of jaundice without gross obstruction required extensive investigation which included examination of the gastric, intestinal, and urinary secretions, and also of the blood. When jaundice was traceable to portal infection treatment by a vaccine was of considerable value.

Dr. H. PEMBERTON said that apart from a grossly obstructive type of jaundice, which showed acholic stools, bile pigments always in the urine, and an excess of bilirubin (giving the direct Van den Bergh reaction) as well as of bile-salts in the blood, there was another group to which the term "non-obstructive" had been loosely applied. In this group bile-derivatives might be normal or in excess in the fæces, bile-pigments might be absent from the urine, but urobilin was often present, and in the blood there was a form of bilirubin which gave the indirect Van den Bergh reaction, but usually no bile-salts. Among the many types which comprised this latter group a subdivision into a type presenting mainly hæmolytic features and a type presenting mainly primary hepatic inefficiency often seemed possible; in the first type the presence of splenic enlargement, increased fragility of erythrocytes and urobilinuria often contrasted with the condition found in the second type, where lævulose estimation in the blood after a test-meal might show the abnormal curve of liver inefficiency. As a diagnostic test Van den Bergh's reaction did not seem of much value in this respect.

Dr. GORDON GULLAN said that he had seen a typical case of nervous jaundice occurring in a student every time he went up for examination; the jaundice was very deep and lasted for four or five weeks. Dr. Gullan referred to cases of Hanot's cirrhosis in which, as well as the jaundice and the great enlargement of the liver, hæmorrhages were present under the skin and the mucous membranes; in these cases some bile was also found in the stools.

CARDIFF MEDICAL SOCIETY.

A MEETING of this Society was held on April 10th, Dr. E. E. BRIERLEY, Vice-president, being in the chair.

Mr. T. E. HAMMOND read a paper on the

Surgery of the Prostate.

He said that little was known of the cause of senile enlargement of the prostate. The trouble to which an enlarged prostate might give rise could be regarded from three points of view: (a) changes which take place in the tumour itself; (b) secondary effects on the urinary apparatus; (c) the symptoms and complications. As to changes in the tumour itself, about 16 per cent. of tumours removed as simple adenomata showed malignant changes. As to secondary effects, the obstruction to the outflow of urine led to dilata-

tion of the bladder, and later of the ureter and pelvis of the kidney. This gave rise to back-pressure nephritis with retention of urea in the blood, a raising of the blood pressure, and arterial changes. An impairment in the general health and the mental faculties soon followed, while uræmia was usually the cause of death. As to symptoms and complications difficult micturition was often present, but frequency might be equally distressing. The chief complications were acute retention and infection.

Treatment.—Urinary sedatives had a temporary effect on the symptoms, but did not prevent the insidious destruction of the kidney tissue. Extracts of the prostate or of the endocrine glands were useless. X rays and radium had their advocates, but it was difficult to understand why they should have an action on such a deeply situated organ as the prostate, when they had failed in similar conditions found in the more superficial breast. The results claimed were due probably to a failure to recognise the irregular course which many of these cases run, for there might be complete remission of symptoms apart from any treatment.

Three methods of treatment are available: The use of the catheter, forage of the prostate, and removal of the prostate. Catheter life was painful, gave only slight relief, and should be reserved for cases where operation is refused or is contra-indicated. Forage, the term applied to the formation of a channel through the prostate, had been revived lately through the introduction of the Brown-Buerguer cysto-urethroscope and diathermy; in cases of enlargement of the middle lobe alone the functional result was often good, but the method was useless if the lateral lobes were enlarged. Suprapubic prostatectomy gave a perfect functional result. The mortality rate was 8 per cent. for hospital patients and 3 per cent. for private patients. The earlier the operation, the less the suffering and the risk to the patient. Age in itself formed no barrier to operation. Diabetes, heart and lung conditions must be given great weight, since the operative risk is increased and the expectation of life is diminished, but debility was not necessarily a contra-indication. Difficulty and frequency called for treatment. Exaggerated sexual desire was often distressing, and, in cases where elderly men were arrested for accosting women in the parks, an enlarged prostate was often the indirect cause of the trouble. Infection would never clear up until the prostate had been removed.

The open operation, introduced by Sir John Thomson Walker, was, in Mr. Hammond's opinion, the operation of choice, but where the general health was not good he performed the older type of operation. When signs of renal inefficiency were found the prostate should be removed only after preliminary drainage of the bladder. Suprapubic prostatectomy should be reserved for the simple or so-called adenomatous enlargement; it should not be performed where the prostatic symptoms are due to a malignant prostate, a chronic inflammatory prostate, a small fibrous or irritable prostate, or a prostatic bar.

Dr. JAMES BEATTY gave a demonstration of

New Instruments for Obtaining High Microscopical Magnifications.

He showed two eye-pieces of his own invention which were infinitely variable in power within their upper and lower limits. He pointed out that these could be usefully used only if the capabilities of the microscope were thoroughly understood. There was an optimum distance of objective from object for every objective. The best possible image would only be obtained when the objective was in this position, and the maximum cone of light that the objective would stand was entering it. This critical image could only be obtained if certain conditions, outlined by Dr. Beatty, were present. The new appliances shown were meant to be used only on the critical image, and the merit claimed for them was that a microscopist possessing one or other of them and Nos. 2 and 4 eye-

pieces (and an extra No. 2 in the case of one of the new instruments) could obtain any magnification whatever producible by eye-piecing from about $\times 9$ to about $\times 40$. In one of them two eye-pieces were used, one acting as an objective; in the other a concave lens was used to produce the variation in magnification. By working with the critical image and varying the power of the eye-piece as required within the limits that the image would stand much of the work at present done with an oil-immersion 1-12th inch lens could be done with a 1-6th inch.

BATH CLINICAL SOCIETY.

A MEETING was held on April 6th. Mr. W. G. MUMFORD, the President, being in the chair, when a discussion was held on

Indigestion, its Varieties and Treatment.

Dr. C. S. FLEMMING spoke from the point of view of the general practitioner. He dealt with the question of pain, which is so frequently complained of by patients, and is so difficult to explain. He also raised the questions of the efficacy of various diets and of the administration of alkalies.

Dr. F. G. THOMSON, speaking as a physician, defined the term indigestion as a condition involving pain, eructation of gas or sour fluid, and vomiting. He dealt with its treatment both by general means and by drugs. He pointed out the association of dyspeptic symptoms with oral sepsis, pulmonary tuberculosis, and cardiac disease.

Mr. F. FRASER spoke from the standpoint of the surgeon. He remarked on the failure to diagnose cancer of the stomach in the early operable stages, and indicated the signs of this condition which he had found reliable. Of these continuous pain was the most prominent. He then dealt with the unreliability of the differential diagnosis of the various surgical cases showing symptoms of dyspepsia.

The discussion was continued by Dr. C. EDE, Dr. C. A. MARSH, and Dr. D. A. MITCHELL, who dealt with duodenal ileus; Dr. H. C. HEATHCOTE and Dr. R. G. GORDON, who dealt with dyspepsia of psychogenic origin; and Mr. J. H. NIXON, Dr. V. M. COATES, and Mr. C. H. TERRY.

ABERDEEN MEDICO-CHIRURGICAL SOCIETY.

A MEETING of this Society was held on April 5th, Dr. ALEX. OGSTON, the President, being in the chair. A lantern demonstration on Pelvic Hernia (Prolapsed Uteri) was given by Mr. ALEXANDER DON and Mr. VICTOR DON. The anatomy of the pelvic floor was shown, and the authors pointed out that the real support was formed by the levators, coccygei, &c., and their coverings the true fascia of the muscles. Sections of the pelvis showed the subperitoneal tissues impregnated with fat with no definite ligamentous bands. The physiology affecting the abdomino-pelvic pressure was fully explained, showing that gravity had little to do with prolapse, or the so-called ligaments with retention of organs, the onus being entirely on the pelvic muscles and their fascial coverings. A new operation founded on the methods which have proved successful in dealing with herniæ elsewhere was demonstrated, in which the edges of the levators were brought together and their fascial coverings overlapped; or, if these were found much scarred or thinned, a piece of fascia lata from the thigh was introduced to strengthen the support. Operations which depended on the suturing of connective tissues only were condemned as unreliable. The authors have not had sufficient experience of the results, but the operation was stated to be comparatively simple and safe, and healing was ensured by gentle handling of the tissues.

Reviews and Notices of Books.

THE PHYSIOLOGY OF TWINNING.

By H. H. NEWMAN, Professor of Zoology in the University of Chicago. University Press, Chicago. 1923. Pp. 230. \$1.75.

THIS very interesting book is a sequel to the Biology of Twins by the same author published in 1917. It deals only with "true" twins—that is, pairs of individuals derived from single eggs—and covers the whole animal series instead of being limited to mammals, as was the former book. Such a process of reproduction occurs normally in earth-worms, as was discovered by Kleinenberg nearly 50 years ago, and to an extraordinary degree in some armadillos. In the Texas armadillo (*Dasypus novemcinctus*) the early embryo divides into two symmetrical longitudinal halves, and each of these divides again, so that normally four "identical" young are produced from a single egg. In a South American species (*D. hybridus*) three such twinnings are normal and a fourth may occur, so that as many as 12 embryos may arise from one egg. In man the same process may result in two separate individuals; this is represented by the familiar identical twins of the same sex with one placenta. Or at the other end of the scale one of the individuals may be represented by a teratoma, and presentations of all the intermediate stages are found in Siamese twins, the various double monsters, the rare condition of hemihypertrophy, and probably in transpositions of the viscera, one of the two mirror-imaging individuals being in this last case suppressed. In making his survey of the subject the author is concerned to emphasise two points. He insists that double embryos are always produced by fission from one egg rather than by fusion from two. Fission may take place at any stage of early development—by division of the blastoderm, by double gastrulation, or by partial or complete separation of the halves of a single embryonic axis. And in discussing one case after another he always brings forward his generalisation that the fundamental cause of twinning is a lowered rate of metabolism and growth during which the embryo loses the functional orientation to which recent experimental zoologists attach so much importance. Arey has recently pointed out that monozygotic human twins are much more frequent in tubal than normal pregnancies. It is curious that Prof. Newman says that double monsters are unknown among mollusca; Pelseneer has published many examples of double and multiple embryos.

For its substance the book is perhaps rather over-long. We would indeed suggest that when a new edition is called for it would be better to reduce this and the author's previous work to a single volume, which would then be an extraordinarily useful and suggestive book to workers in many fields.

REGIONAL ANÆSTHESIA.

By GASTON LABAT, M.D., Lecturer on Regional Anæsthesia at the New York University. London and Philadelphia: W. B. Saunders Company. 1922. Pp. 496. 35s.

CERTAIN drawbacks have arisen from the high state of perfection which the art of inducing general anæsthesia has reached in this country, the chief of which is that but little attention has been paid to the possibilities of local anæsthesia. There are few English surgeons or anæsthetists particularly skilled in all the methods of regional anæsthesia. In general its possibilities are unknown. A perusal of this book shows how carefully the technique has been worked out and how it may be employed for almost any operation. It is obviously more easy to employ these methods in patients of the stolid unimaginative kind, for the injection of the anæsthetic itself would be very disturbing to the highly-strung individual;

such a one would scarcely submit to the 12 or 14 needle-pricks which are necessary for a laparotomy in order to block the abdominal nerves in front and the splanchnics behind. But often in old weak people or when there is the toxæmia of acute intestinal obstruction, regional methods have many advantages, and fortunately such patients have dulled sensibility. In other parts of the body local anæsthesia is more easy to induce and correspondingly more useful. The author is very clear in his descriptions of technique, the book is beautifully illustrated, but a statement of the percentage of failures in such methods as paravertebral and splanchnic anæsthesias would have rendered it even more valuable. The latter procedure is apt to fail in the most skilled hands.

For those who wish to practise regional anæsthesia this book is as good a guide as any in the English language.

THE CAPILLARIES.

The Anatomy and Physiology of Capillaries. By AUGUST KROGH, Ph.D., LL.D., Professor of Zoö-Physiology, Copenhagen University. (Silliman Memorial Lecture.) London: Humphrey Milford. Oxford University Press. 1922. Pp. 276. 13s. 6d.

ALTHOUGH the capillaries represent the most important part of the circulation, it is surprising that accurate investigation of their properties has been deferred until the present decade. Although Prof. Krogh, with characteristic modesty, would have us infer that his own researches in this field are merely an extension of the work of various earlier investigators, physiologists recognise him as a real pioneer, because his writings have so beautifully integrated the experimental results of his predecessors as well as adding much of great significance to their achievements. If any object-lesson were needed of the folly of divorcing histology and biochemistry from the purview of biology and physiology, we have it here, for Prof. Krogh has viewed his problem from all these standpoints, and achieved results unattainable from any single one. The book, written in English of which the author may well feel proud, marks an epoch in the physiology of the circulation, and should be read by all clinicians who view their subject from the scientific aspect, as it will certainly be read by physiologists all over the world. Our congratulations are extended, not only to the author, but to the Silliman Trustees, on their choice of lecturer.

FOOD VITAMINS.

Vital Factors of Foods, Vitamins, and Nutrition. By CARLETON ELLIS, S.B., F.C.S., Consulting Chemist, author of "Hydrogenation of Oils," &c.; and ANNE LOUISE MACLEOD, Ph.D., Associate Professor of Chemistry, Vassar College. London: Chapman and Hall, Ltd. 1923. Pp. 391. 25s.

THERE are so many books dealing with vitamins already on the market, that it is a little difficult to understand the motives which prompt authors to add to their number. The present book is quite as good as many of its contemporaries, and provides a satisfactory account of a subject which is in danger of becoming rather dull from over-emphasis and vain repetition. The account given in this volume appears to be complete and well written, though the historical perspective does not seem always to be accurate; the method of treatment adopted is to give abstracts of the work of most of the investigators who have given attention to the subject; where views conflict, the reader is left to choose between them for himself. The book is thus more valuable as a guide to the literature on the subject than as a digested presentation of results. The literature quoted is especially full, and is given not only by footnote references, but also in the form of a classified index of results showing the distribution of vitamins in an incredible variety of foodstuffs.

LECTURES ON DIETETICS.

By MAX EINHORN, M.D., Emeritus Professor of Medicine at the New York Post-Graduate Medical School and Hospital; Visiting Physician to the Lenox Hill Hospital, New York. London and Philadelphia: W. B. Saunders Company. 1922. Pp. 244. 10s. 6d.

THIS is a revised and enlarged edition of a series of post-graduate lectures on dietetics. General principles rather than detailed regimes are dealt with, and on this the writer may be heartily congratulated, for it saves his book from the dogmatism which makes many larger volumes illogical and unreadable. Special chapters on duodenal and rectal feeding are of great practical value, and the short account of the Allen treatment of diabetes is well written. We regret that Prof. Einhorn has not devoted a special chapter to peptic ulcer, but doubtless he feels the subject too vast to be compressed into a small volume of this type.

GREEN'S MANUAL OF PATHOLOGY AND MORBID ANATOMY.

Thirteenth edition. Revised and enlarged by W. CECIL BOSANQUET, M.A., M.D., F.R.C.P., Physician (late Pathologist) to Charing Cross Hospital, &c., and G. S. WILSON, M.D., M.R.C.P., D.P.H., Demonstrator in Bacteriology, Charing Cross Hospital Medical School. London: Baillière, Tindall and Cox. 1923. Pp. 624. 21s.

FEW text-books have enjoyed so successful a career as Green's Pathology. For over 50 years it has been in demand among medical students, and its popularity shows no signs of declining. Its vogue is easily explained. Without being unduly bulky, it contains sufficient to meet the needs of the qualifying examinations, and successive editors have modernised it without robbing it of those features which originally distinguished it from other manuals on the same subject. The present edition has been extensively revised and rearranged, and additional matter incorporating the work of the last few years has been inserted where necessary. There are also several new figures, though some of these are hardly as good as they might be. The book is well bound and printed, and is, for a post-war publication, extremely cheap.

THE ANIMAL AND ITS ENVIRONMENT.

A Text-book of the Natural History of Animals. By L. A. BORRADAILE, D.Sc., Lecturer in Zoology in the University of Cambridge. London: Henry Frowde and Hodder and Stoughton. 1923. With 426 text figures and 4 coloured plates. Pp. 399. 18s.

BIOLOGY is just now maintaining a place in the medical curriculum with some difficulty and has long occupied a strangely minor position, though medicine cannot be other than a branch of applied biology. Of the value of a sound discipline in morphology and of the educational work of the larger conceptions of comparative anatomy there can, however, be no question; and if to these formal studies there had been added more of the sort of biology dealt with by Dr. Borradaile, projects to relegate the subject to a subsidiary position in the physiological department would be treated with contempt. The archaeological fascination of unravelling the past has had an undue share of attention; we are told even now that the object of studying embryology is to elucidate descent.

The modern development of interest in the relations of live animals and plants to one another and to their present surroundings has not yet been adequately reflected in the elementary curricula. Dr. Borradaile's work is therefore very welcome. With hardly any reference to evolution—well catered for already—he deals in order with the relation of animals to their physical surroundings and to animals of the same and different species, with the characteristics of marine,

fresh-water, and land animals, with parasites and other similar topics. The subjects are, of course, of vast extent and the treatment is therefore necessarily condensed and nowhere exhaustive; the chapters would, indeed, make excellent frameworks for courses of lectures. Planned primarily for students, the book needs close reading, and the quantity of information contained in it is very considerable. It is also suggestive to a high degree, and we can imagine that the reader will often want to know where he could find more about this or that topic. Unfortunately, there are practically no references; indications of the existence of such books as Murray's "Ocean" in the Home University Library, Poulton's "Colours of Animals," Flatteley and Walton's "Biology of the Sea-shore," L. J. Henderson's "Fitness of the Environment," and so on would be very useful to the student who has no advisers ready to hand. The illustrations are abundant and with their legends supplement the text a good deal; some of them are very old friends, but their varied nature adds to the excitement and interest of the book.

MALAY POISONS AND CHARM CURES.

Second edition. By JOHN D. GIMLETTE, M.R.C.S., L.R.C.P., Residency Surgeon of Kelantan. London: J. and A. Churchill. 1923. Pp. 260. 8s. 6d.

WHEN IN THE LANCET of May 22nd, 1915, we reviewed the first edition of this excellent book we expressed a wish that Mr. Gimlette would continue his researches into Malay poisons, and we congratulate him on the fact that he has done so. In this edition, to which Sir W. H. Willcox has written a foreword, the author goes considerably more fully into the subject. Kelantan, and we daresay other portions of the Malay Peninsula, must be a paradise for the poisoner, so many and so varied are the poisonous animals, insects, and plants. Sir W. H. Willcox mentions in his foreword that 18 animal poisons and 23 vegetable poisons have as yet their active principles undetermined. Mr. Gimlette mentions one method of administering poison which was commonly used, so tradition says, in the Middle Ages in Europe—namely, by dividing a fruit or a melon with a knife, one side of which has been smeared with poison, cyanide being generally used in Trengganu, which borders on Kelantan. Among the vegetable poisons used are the sap or the resin of trees known as Jitong and Rengas. Workers in Rengas wood are liable to painful eruptions on the skin caused by sawing the wood and a similar effect has been noticed and was commented on not long ago in the case of workers in other woods. Mr. Gimlette's chapters on spells and charms are of extreme interest as showing, among other matters, how consistent human nature is from age to age. For instance, on p. 45 is an account of a "bomor"—i.e., a Malay medicine-man—who treated the pain caused by a bite from a non-poisonous snake by blowing on the bitten limb. Mr. Gimlette quotes from a writer to the *Times* of 1919 an account of a herbalist in the East-End of London who cured scalds by blowing on the blisters, and a similar story comes from Belfast and is given in the *Daily Express* of Jan. 23rd, 1923. In this case, however, the child died from sepsis. On p. 96 we have an account of the old old superstition of the waxen image made in the likeness of the person whom it is desired to slay, and pierced with pins. The value of Mr. Gimlette's book is increased by the full bibliographical references at the end of every chapter and by an admirable index.

JOURNALS.

BRITISH JOURNAL OF EXPERIMENTAL PATHOLOGY. Vol. IV., No. 2, April, 1923.—On the Behaviour of Platelets in Vitamin-A Deficiency and on the Technique of Counting Them. W. Cramer, A. H. Drew, and J. C. Mottram. The authors confirm their

observations that there is a constant deep thrombopenia in vitamin-A deficiency, which they now suggest is due to adsorption of platelets by bacteria which enter the body through the intestinal tract. They discuss S. P. Bedson's and S. S. Zilva's criticism of their work and conclude that these authors have used a faulty optical system in their microscopic technique.—A Suggested Substitute for Canada Balsam as a Mounting Medium, H. W. Southgate. Yucatan Elemi is recommended as a substitute for Canada balsam, over which it has distinct advantages, one being the better retention of colours in preparations mounted in it.—Growth and Differentiation in Tissue Cultures, A. H. Drew.—On the Mode of Production of Bacteriophage, Elizabeth H. Lepper. The strength of a given bacteriophage is not increased by allowing it to kill and lyse sensitive bacilli, but there is some evidence that increase in lysis is associated with proliferation of the resistant type of bacillus; the experiments on which these and other conclusions are based are described in detail.—The Detection of *Spironema Pallidum*, J. E. Barnard. An important point in the recognition of *S. pallidum* is the relation of the number of spirals to a given length, and a convenient unit of length is the diameter of the erythrocyte. Since red blood corpuscles are not always abundant in the material to be examined, the author has devised a graticule which, if placed on the diaphragm of the ocular, produces in the microscopic image clear circles which imitate accurately red blood corpuscles.—Investigation of the Aetiology of Typhus Fever, especially undertaken for the Egyptian Government in the Public Health Laboratories, Cairo, J. A. Arkwright and the late A. W. Bacot. The virus of typhus in blood is found in much greater concentration in a platelet emulsion than in other parts of the blood. Lice infected with *R. prowazeki* are infective for guinea-pigs whether an emulsion of the lice themselves or of their excreta is used for the inoculation. The excreta of such lice remains active as a dry powder at room temperature for 11 days. While there is no evidence that rickettsia can be transmitted by the lice in the act of biting, the virus in the faeces can enter the body through abrasions, &c.—The Brain and Immunity Reactions to Jensen's Rat Sarcoma, W. S. Lazarus-Barlow and R. H. Parry. Intracerebral inoculations of non-radiated or heavily-radiated grafts produce a general resistance to inoculation greater than that brought about by subcutaneous inoculation of similar material. The growth of a graft in the brain is restrained and delayed as compared with one in the subcutaneous tissue.—The Relative Concentration Ratios of Some Constituents of the Urine, S. W. F. Underhill. Urea and creatinine are evenly distributed between the plasma and the corpuscles in the blood of the cat, but after injection of these substances into the blood stream there may be a greater proportion in the plasma. A larger proportion of injected inorganic phosphate and uric acid is found in the plasma than in the corpuscles.—Vascular Changes Affecting Bulbar Nerve Centres, D. T. Barry. An investigation into the variations in tone and excitability of bulbar centres brought about by changes in the supply and in the hæmoglobin content of the blood.

THE TROPICAL DISEASES BULLETIN for March contains reviews of recent literature on yaws, tuberculosis, and helminthiasis. Ten papers on yaws are summarised by A. G. Bagshawe, including the recently published clinical study by R. L. Spittel. Tuberculosis in the tropics, an extensive and very important subject, is discussed in a series of 20 reviews by S. L. Cummins, who draws the attention of tuberculosis specialists in this country to this important aspect of the subject, and as he remarks, one is apt to regard the disease solely from their standpoint, not recognising that the manifestations of tuberculosis in the tropics differ considerably from those seen in temperate climates. A total of 165 papers on helminthiasis are summarised for the most part by R. T. Leiper, assisted by H. Harold Scott.

INSULIN AND THE TREATMENT OF DIABETES: SOME CLINICAL RESULTS.

A REPORT TO THE MEDICAL RESEARCH COUNCIL.

WE have published in these columns the announcements from the Medical Research Council¹ explaining the measures which have been taken in this country for studying the production and the properties of insulin, and for promoting its manufacture upon a large scale. The last of these announcements promised the communication to the medical profession at an early date of the results of the treatment as now, and for the past months, in progress at various hospitals, so that the experience gained in the clinical researches should inform and guide the profession.

The present statement is, accordingly, a clinical report upon the uses of insulin, and is the outcome of a conference held at the offices of the Medical Research Council. It gives a general summary of the clinical experience of workers in various clinics in London (University College, the London, St. Bartholomew's, Guy's, St. Thomas's), Sheffield, Edinburgh, and Glasgow, these being the centres at which the Council had organised a local laboratory production of insulin and its clinical study. The workers had the advantage of using insulin prepared, under the directions of the Medical Research Council, in the laboratories of the medical schools attached to each hospital, and have been in close coöperation with workers at the National Institute for Medical Research. Latterly samples of insulin prepared by commercial firms have also been used for these clinical investigations, and the results have been found to be identical with those obtained from the products of the various research laboratories.

EXTENT AND NATURE OF CLINICAL TESTS.

The clinical workers have nowhere attempted the quick treatment of a large number of diabetics. At each hospital they have tended rather to select two or three severe cases of this disease and to study very closely the influence of insulin upon the patients week by week, following out the changes in blood-sugar, in respiratory exchange, and in general metabolism, all in great detail with reference to a dietary controlled by precise measurement. The ultimate results of these investigations may throw light upon the metabolic derangements underlying the phenomena of diabetes, and individual papers relating to this work at the various research centres will doubtless appear in course of time. But other physicians wishing to begin the treatment of patients with the insulin that is now available from commercial sources may find some help in an account that presents the general experiences of those who have hitherto been using the product in this country.

Insulin has been used clinically at eight different hospitals for a period of study of about three months at each. The total number of diabetics treated has been small, less than 50, and it included only seven examples of coma. Except in the cases of coma, the patients have all shown admirable improvement, just as was described by the Canadian workers. The blood-sugar falls rapidly as the temporary result of each injection, and sugar may be prevented from appearing in the urine even on a diet so generous as to be three- or four-fold as great as that which the patient could previously tolerate. There is a steady increase of weight together with a sense of greater warmth and energy. The phenomena usually ascribed to deficient metabolism of fats are especially influenced. Acetone vanishes from the breath and aceto-acetic

acid from the urine; lipæmia disappears; acidosis and dyspnoea are at once controlled. It is, however, necessary to insist, by way of caution, that these immediately satisfactory results have been obtained only with insulin. Some other commercial extracts of the pancreas that may at present be bought in the market, for hypodermic or other forms of administration, were tested and found to be totally inert in respect of any power to produce the least fall of blood-sugar, even in a rabbit.

No substitute has yet been found for the hypodermic method of giving insulin. The injections have to be repeated at least once each day. They can control all the ordinary phenomena of diabetes, but the effect of each injection is only transient. As yet there is no satisfactory evidence—time has hardly allowed of that—to show that diabetes in its most serious forms can be completely cured by insulin. It may be that the great majority of severe cases cannot hope for more than prolongation of life, with greater strength and ampler dietary, but only at the cost of continuous treatment with insulin.

GENERAL PRINCIPLES OF ADMINISTRATION.

The insulin is procured by alcoholic extraction of pancreas from the abattoirs. By a complicated alcoholic fractionation, and other processes of fractional precipitation, the active constituent is obtained in a state of relative purity, and is put up in sterile watery solution with a trace of antiseptic added. Ampoules of solution should be kept in the cold wherever possible. The injection should be made with a fine needle, preferably under the skin of the upper arm. A slight tingling or discomfort may be caused for a few minutes, but no prolonged effects of local irritation or reaction have occurred, and the same place may be used again and again for injections.

The unit dose is not measured by reference to the weight of substance taken into solution, but by determining the volume of final solution required to reduce the blood-sugar of a 2-kilo. rabbit under standard conditions to about 0.04 per cent., at which level convulsions appear. Three units, as at present defined, produce this effect in a rabbit; or the units may be calculated by observations on mice under similar standard conditions. The average single dose for an adult patient is 10 new style units, but the administration should always be guided by thought in units rather than in the so-called doses.

In a healthy subject, starved previously for 15 hours and remaining without food, 30 units will cause a fall of blood-sugar commencing in less than half an hour and progressing for about three hours. The fall may be from the normal level of about 0.12 per cent., or 0.1 per cent. down to 0.06 per cent., near which level definite and serious features of sugar deficiency are likely to appear. A larger dose of insulin is required to produce this critical fall in the healthy human being, where the liver is full of stored glycogen, than is an emaciated diabetic. In the latter a rapid fall in blood-sugar and the development of hypoglycæmic features do occur much more readily.

The similarly produced insulin hypoglycæmia in a rabbit is attended by convulsions, coma, and muscular flaccidity. The rabbit remains apparently moribund, and without treatment may die in an hour or two; but the intravenous injection of glucose solution at this stage will in a couple of minutes restore an unconscious and convulsed animal into an apparently normal creature that will probably begin at once to nibble food again. Subcutaneous injection of glucose solution is equally effective, though 10 or 15 minutes are then needed for recovery. The parallel phenomena of insulin hypoglycæmia in the human patient are described later. They can be checked at once by the administration of glucose, but their occurrence should be avoided altogether by carefully attending to the time when insulin is given in relationship to food.

¹ THE LANCET, Nov. 17th, 1922, Feb. 21st and April 21st, 1923.

Administration in Relation to Food.

Insulin should never be given during periods of abstinence from food. Glucose reaches the blood very soon after a meal, and continues to do so for two or four hours, varying with the nature of the meal, whether carbohydrate or protein. The effect of insulin lasts for a period up to eight hours, but there is little danger of serious features developing after the fifth hour. Therefore each injection should be followed by a meal in about a quarter of an hour, and fresh food should be given every three or four hours subsequently until the insulin effect has passed beyond such activity as might reduce the blood-sugar to a seriously low level. It is obviously safer to give two small doses at fully spaced intervals rather than one large dose daily, and a large dose should never be given in the evening, for serious changes might arise unnoticed during the time of sleep and abstinence from food. One worker found that 1 unit of insulin could provide for the efficient consumption of 2 g. carbohydrate taken as such in the food of a completely diabetic patient. Protein food contains nearly half its weight of potential carbohydrate, so that the same dose of insulin should provide for at least 4 g. of protein. But the carbohydrate from protein enters the blood much more slowly than does that of carbohydrate food taken directly as such. Moreover, diabetic patients vary greatly in the amount of insulin required to cover the food taken, while even the individual patient may vary from time to time in his needs.

It is therefore impossible at present to state the doses of insulin needed in respect of any scale of diet. Each patient must be tried separately with regard to his own individual requirement, and the dosage subsequently watched for possible changes in the amount needed.

DANGER OF HYPOLYCEMIC COLLAPSE.

The results of an excessive dosage of insulin were rarely seen. At two of the centres there was no experience at all of them. Other workers saw them to a moderate degree, particularly in cases where diabetic patients were given insulin during periods of starvation for the purpose of studying its influence on the standard metabolism. The reaction, which usually appeared three or four hours after insulin injection, commenced often with a sense of weakness, sometimes associated with free perspiration. Faintness, dizziness, and mistiness of vision were added to this; and the patient might either feel drowsy, as though going quietly under an anæsthetic, or show intense anxiety from the sense of rapidly advancing and overwhelming weakness. The nervous reflexes were simply depressed but not otherwise changed. The blood-sugar was then usually down to 0.06 or 0.05 per cent. Prompt recovery in 10 or 15 minutes was easily obtained by giving glucose from 10 to 20 g., or about $\frac{1}{2}$ oz. drunk in 3 or 4 oz. of water.

Cases that through lack of proper vigilance might have been allowed to pass into unconsciousness would require subcutaneous or intravenous injections of glucose solution (5 per cent. in normal saline). Milder cases at the onset of collapse can be treated by cane sugar. Glucose is not essential except for intravenous injection. No fatalities from this cause have been observed in Great Britain, and the experience of the first three months would suggest that the danger from it is slight. That happy result is, however, not to be taken as evidence that the danger is negligible, but rather to be ascribed to the close attention that was given daily to those patients and to the repeated measurements of their blood-sugar curves. Unnoticed changes in the sugar variation of a diabetic might easily occasion a serious insulin collapse; or the reaction might follow from some quite trivial chance, such as a patient for some reason or other leaving uneaten the meal that was ordered to follow an injection of insulin.

An Illustrative Case.

An instance that did occur in one hospital ward recently may be quoted in full, since it illustrates emphatically the great need of care in using this new and powerful method of treatment.

CASE A.—A man, aged 62, who had suffered from diabetes mellitus for seven years. He was greatly emaciated. He had ataxia of the legs, the knee-jerks were absent; he presented Romberg's sign and optic neuritis. The Wassermann reaction was negative. There was no evidence of cerebral tumour. During nine days after admission the patient was kept on 53 g. of fat, 84 g. of protein, and 107 g. of carbohydrate, in order that his ketosis might improve. This it rapidly did. He retained on the average about 50 g. of carbohydrate, the urine-sugar averaging between 50 and 60 g. per diem.

April 4th. The fasting blood-sugar was 0.33 per cent. The administration of insulin began, 10 units being given three times a day. Diet consisted of 108 g. carbohydrate, 85 g. protein, and 54 g. of fat. The urine on this date became free of sugar.

April 5th. Thirty units of insulin. At 3 P.M. patient says he has been perspiring since 2 P.M., especially noticeable on the head. He feels rather sick and irritable, but seems quite well.

April 6th. Yesterday's urine was free from sugar and acetone. Usual dose insulin 10 units given at 6 A.M. Patient feels well this morning, but is even more hungry than usual. Feels quite well but rather tired. 1 P.M.: 10 units insulin given. Usual dinner. 2.30 P.M.: The patient got up to shave and wash. He returned to bed about 3 P.M., and felt a glow going all over him and he began to perspire, felt slightly sick and very irritable. At 3.30 P.M. he had a short sleep—he said he had a feeling of apprehension. 3.45 P.M.: The patient awoke in a violent rage, swearing and shouting at another patient in the room for no apparent reason. He was perspiring profusely. Eyes staring. Speech very thick. No twitching. Pulse feeble but not rapid. Whisky 1 oz. in 180 c.cm. hot water given. Patient drank this easily and said he felt better, though he began to feel shivery. Face looked very congested and veins on temples were very prominent. Pulse improved after the stimulant, but patient gradually became more helpless and said he felt "drunk." Saliva dribbling. 4.10 P.M.: The patient cannot hold his head straight (fall to right side), great difficulty in swallowing, the tea coming down his nose. He ate half an egg and a little tea (usual dose of insulin not given). At 4.15 P.M. he was much paler, skin still very moist and cold; cannot speak at all. Unable to swallow. 5.15 P.M.: Patient quite unconscious; incontinence of urine. Blood taken for sugar=0.09 per cent. Moaning continually, with occasional very loud groans (almost a roar). Cannot swallow glucose prepared. 6 P.M.: Intravenous injection of glucose, 45 g. in 450 c.cm. normal saline solution. 6.5 P.M.: Groaning stopped, and patient opened his eyes and became very restless. 6.10 P.M.: Consciousness regained; dribbling of saliva stopped. Patient began to speak, saying that his throat was sore and he felt very cold. Glucose, 25 g. in 240 c.cm. water, and lime-juice given by mouth and swallowed easily. 7 P.M.: Patient sitting up in bed, feeling well and hungry and much warmer. He remembers nothing from the time when his tea was brought in at 4 P.M. until 6.30 P.M. He remembers the onset of the attack very distinctly, and says he knows he lost all control and was shouting and swearing when the attack came on. He says the irritability seemed to "come over him in waves," leaving him with a feeling of nausea. 7.15 P.M.: Patient ate supper—egg, cauliflower 100 g. oatcake 30 g., butter 15 g., two cups of coffee, cream 60 c.cm.

April 7th. Patient feeling very much better. On previous day the urine contained 6 g. sugar, although 154 g. carbohydrate, 74 g. protein, and 108 g. fat had been taken in his diet.

Since April 8th only small traces of sugar have appeared in the urine, in spite of the diet consisting of between 140 to 150 g. carbohydrate, 78 g. protein, and 150 fat. There has been a steady improvement, blood-sugar remaining at about 0.150 per cent., but on a number of occasions there have been signs of hypoglycæmia. These usually occurred in the late afternoon. The amounts of insulin vary between 20 and 30 units per day. It is apparent in this case that symptoms due to hypoglycæmia occurred very readily as during the severe attack the blood-sugar had only decreased to 0.09 per cent.

If insulin be given to patients in such amounts as to keep the urine free from sugar the dosage must be frequently checked by blood-sugar determinations. And for all cases under insulin treatment glucose or cane-sugar must be kept ready at hand, so that a small quantity may be given to the patient as soon

as any premonitory symptoms of hypoglycæmia are noticed.

SELECTION OF PATIENTS.

The instructions drawn up by the Committee advising the Ministry of Health upon the use of insulin require that there shall be no luxury use of this product until supplies are abundant. Mild cases of glycosuria or diabetes are therefore excluded, and with these would automatically be classed those cases (renal glycosuria) where sugar is present in the urine for three or four hours after food, owing to excessive permeability of the kidney, though the blood-sugar is not raised above the normal percentage, and the patient remains otherwise in good health.

It is obvious that whenever insulin becomes available for the treatment of mild cases, great care will need to be exercised in the exclusion of such cases of renal glycosuria from insulin administration since they would be likely to show early and dangerous hypoglycæmic collapse. All ordinary diabetics should, in the first place, be put on a restricted diet with some periods of starvation—as, for example, by the Allen or Graham procedure—and their treatment continued simply in this way on the lines established by workers in the years immediately preceding the introduction of insulin.

If the diabetes is not of long standing and the patient not greatly wasted, this treatment would probably suffice, or might need only slight assistance later with insulin. But if the disease is of long duration, with proved excess of blood-sugar, and the patient fails after starvation to tolerate any diet of less value than about 1000 calories in the 24 hours, so that strength and weight continue to fail seriously, then insulin should be given systematically.

The cases hitherto treated at the research centres have all been of this severe type. The reasons for this choice were two: In the first place, the supply of insulin made at each hospital laboratory was small, and it was naturally reserved for those patients who were so seriously ill that without the aid of the new treatment they could not have been expected to live many months longer. Secondly, these serious cases, in whom failure of ordinary treatment by dieting over a long period had proved the almost complete decay of the patient's natural mechanism for the proper metabolism of carbohydrates and fats, gave an opportunity for demonstrating clearly and at once in each individual case the powerful effect of insulin against the background of complete diabetes. Mild or acute cases of diabetes often recover so well during the first course of dietetic treatment without any aid from insulin that it would have been necessary to study a considerable number of them in order to demonstrate convincingly the effect of insulin.

THE MANAGEMENT OF TREATMENT.

The method of controlling the diet varied in the different centres, and it is needless to discuss the details of this, because every physician has developed in the course of his experience in the treatment of diabetics his own individual rules for the construction of a dietary; and there was only one instance, to which reference is made later (Case E), suggesting that a special arrangement of the proportions of foodstuffs may be combined with the action of insulin in such a way as to lead to a sustained improvement in the patient's own tolerance of carbohydrate. The general experience was that insulin acted simply as a temporary instrument to enable a diabetic to eat a certain amount of more food than he could previously tolerate without the appearance of sugar or acetone bodies in the urine and without a rise in his blood-sugar. Each dose of insulin, therefore, enabled him to get more energy out of the food and to increase the reserve stored up in his tissues as evidenced by increase of weight. Only a progressive increase of weight over several weeks was accepted as proof of tissue increase, for there was reason to believe that part of the increase of weight was due simply to increased retention of water in the body.

Dosage in Severe Cases.

The following cases are quoted, briefly, to illustrate the doses of insulin needed in severe cases:—

CASE B.—Woman, 56 years old, with steadily progressive and very severe diabetes. During the last 18 months she had repeatedly undergone dietetic treatment in hospital, at first with immediate success, but ultimately tolerance could not be established on any diet sufficient to maintain life.

After five days' continued starvation, the urine became sugar-free. The subsequent tolerance was of a diet of only 190 calories in 24 hours.

By the administration of 60 units of insulin each day she was enabled to tolerate 1350 calories daily, with 80 g. carbohydrate, and her weight was raised in ten weeks from 5 st. 10 lb. to 7 st. During the day the urine was sugar-free and contained no acetone bodies on this diet; but each morning the blood-sugar was over 0.4 per cent., and the urine contained sugar and a trace of ketone from the failure of her own unaided metabolic processes during the night.

CASE C.—Man, aged 18, with severe diabetes for three years. On a diet of 600 calories, containing 20 g. carbohydrate, he excreted 30 g. of sugar daily. With insulin, about 12 units daily, he could tolerate a diet of 1400 calories daily, containing 48 g. carbohydrate, the urine being sugar-free and the blood-sugar below 0.2 per cent. His weight and strength have steadily increased.

CASE D.—A very severe case, who had been kept just alive for the two months preceding insulin treatment on a diet of 600 to 800 calories daily. On this he was excreting large amounts of sugar and ketone bodies, and seemed unlikely to survive many weeks. Insulin twice daily enabled such increase of diet to be made that there was a gain of weight of 15 lb. in the first fortnight. He was eventually raised to 2500 calories with 70 g. carbohydrate, upon which, with slight glycosuria, he was able to return to work while continuing insulin injections twice daily.

Aim at Real Amelioration.

The doses in severe cases may be from 10 to 20 or even 30 units twice a day, or a smaller amount divided between three doses. Patients with so grave a form of the disease plainly ought to be treated at first in special institutions, where the diet can be closely controlled and the blood-sugar frequently determined. If, after treatment has commenced, only one measurement of the blood-sugar is made occasionally, it should be from a sample taken at the same time daily and three hours after the injection of insulin and the consumption of a meal directly related to that injection. With such precautions it may be possible to give enough insulin to keep the urine entirely sugar-free, and that condition would seem to be the ideal aim when hopes of ultimate cure or real amelioration are entertained. The essential principle in the treatment of diabetics by diet control alone has been generally recognised to be the avoidance of hyperglycæmia and glycosuria, so that the intrinsic powers of carbohydrate metabolism may be slowly regained in the long period of comparative rest from overstrain. Insulin ought to aid this rest period. But if insulin is given in such amounts as to prevent the appearance of sugar in the urine, there are no means of estimating the full effect of the dose except by watching the blood-sugar. If the latter cannot be done sufficiently often it is probably safer to avoid the danger of hypoglycæmic collapse from too much insulin by reducing the dose to such a level as will just allow the patients a slight glycosuria as a safety gauge. In such conditions the patient will put on weight and recover strength, though on a road that may not be the quickest way to cure.

Real improvement was reported in one case, and here the physician believed that the good result had been attained by the exclusion of all carbohydrate as such from the increased diet under insulin. This method was not tried by the other workers, who had all allowed some carbohydrate food to their patients.

CASE E.—A man with severe diabetes, which had not yielded to rigid dietetic treatment some weeks previously in hospital. On 1360 calories, with 16 g. carbohydrate, he passed from 25 to 33 g. of sugar daily. The blood-sugar at 9 A.M. was 0.24 per cent. He was given insulin, 12 units, each day at 9 A.M. with a meal, the first meal being at 6 A.M. The 9 A.M. blood-sugar gradually fell to 0.15 per cent. It was then found that three hours after 12 units of insulin

the blood-sugar had fallen to 0.055 per cent. The daily dose of insulin was consequently reduced to a lower level at 8 units daily. There was no glycosuria for three weeks and only a small amount of ketone bodies persisted. Subsequently the insulin was reduced to 4 units daily, upon which a diet of 2000 calories, consisting chiefly of protein and fat with carbohydrate as vegetables, is tolerated without glycosuria and with a blood-sugar of 0.11 to 0.13 per cent.

It is obvious that if this dietetic method is proved to be generally applicable there will be a great economy in the use of insulin as well as a better hope of real cure. It is a most expensive method of feeding a patient when carbohydrate is given under the protection of insulin, the latter costing at present nearly 3s. for the control of 30 g. or one ounce of carbohydrate food when eaten by a patient with complete diabetes.

THE TREATMENT OF COMA.

Only seven cases have been treated at the various centres, and they appear to fall into two clinical groups.

Coma following Operation.

First come three cases of coma in diabetes, developing as the result of surgical operations in not very severe diabetics. In all these the blood-sugar during the coma was very high, from 0.7 to 0.8 per cent.; air-hunger and dyspnoea were not conspicuous clinical features, though unfortunately this was not checked by measurements of the alveolar carbonic dioxide or of the alkaline reserve of the blood; there was but little acetone in the breath and not much aceto-acetic acid in the urine. The cases were therefore of coma with great hyperglycæmia, but not with severe ketosis. No improvement was obtained with insulin, though only in one case was the substance given in sufficient amount to reduce the blood-sugar, and it is therefore only in the latter that failure need be admitted. The other two instances should be discarded: in one of them insulin was injected too late when the circulation had practically failed, and in the other the blood-sugar of 0.78 per cent. was virtually unaffected by 30 units of insulin.

CASE F.—A woman of 70, with gall-stones but no obvious liver disease, with arterio-sclerosis and slight diabetes. She passed into coma directly after an operation in which the gall-stones were removed. After five hours of coma the blood-sugar was 0.79 per cent. Dyspnoea moderate, with faint odour of acetone in the breath and only a slight ferric chloride reaction in the urine. No extensor response or other neurological physical signs. Insulin was given subcutaneously in repeated doses of 30 or more units. Five hours later, after a total of 105 units had been given, the blood-sugar was 0.4 per cent. Saline solution had also been given freely. There was absolutely no clinical improvement, and the patient died ten hours later. Post-mortem examination was refused. Clinically the condition appeared to be that of simple coma, though other possibilities cannot be rigidly excluded.

Ordinary Diabetic Coma.

The second group of cases, four in number, was that of ordinary diabetic coma not related to surgical operation, and showing a much lower blood-sugar, 0.3 to 0.4 per cent., but greater air-hunger, with depression of the alveolar CO_2 and with an abundance of ketone bodies in the urine. Further observations are needed before the contrast suggested between the two groups, of surgical coma in diabetes and of ordinary diabetic coma respectively, can be established. But it is obvious that the patients in the second group showed ketosis rather than hyperglycæmia, and in this group three out of four were improved in a very striking way by insulin.

CASE G.—A man was admitted to hospital on the verge of diabetic coma, being just conscious, and with extreme air-hunger as shown by the big respiratory movements of his abdomen and chest. The blood-sugar was 0.33 per cent., a figure often seen in ordinary diabetics while in fair health; but the alveolar CO_2 was 1.1 per cent., a reading so low that in the experience of the physician in charge of the case always meant death within about 12 hours, for he had never seen recovery in any patient with alveolar CO_2 lower than 1.8 per cent. Insulin, 18 units, was given; and abundance of water (15 oz. hourly), together with sodium bicarbonate 2 drachms by the mouth every two hours for three doses. In two hours the patient began to feel better, and his air-

hunger was lessening at the third hour. At six hours the blood-sugar was 0.11 per cent. and the alveolar CO_2 had risen to 2.7 per cent. The patient recovered and now has a morning blood-sugar of 0.15 per cent. on 12 units daily of insulin, and a diet of 53 g. protein, 105 g. fat, and 16 g. carbohydrate in vegetables. There has been no glycosuria for three weeks.

CASE H.—A boy admitted in diabetic coma, with air-hunger and low bicarbonate reserve in the blood. Insulin given, but no sugar. Death.

CASE I.—A young woman of 25, in coma, with air-hunger, acidosis, and blood-sugar of 0.4 per cent. She was given insulin subcutaneously, 10 units, every three hours; at the same time fluid was given freely and glucose solution both intravenously and subcutaneously. The blood-sugar was thereby raised to the very high figure of 1 per cent. The patient recovered.

The last case (Case I) raises a paradox for discussion. Sugar is sometimes given together with insulin in cases of diabetic coma, with the intention of preventing the comatose state from being further aggravated by hypoglycæmic collapse. Now it appears from the cases quoted that coma may arise when the blood-sugar is not unusually high, and also that the patient may emerge from coma though the blood-sugar has been raised by added glucose to 1 per cent. On the other hand, a case (Case F) of post-surgical coma with high blood-sugar was not improved, though the blood-sugar was reduced to 0.4 per cent. by insulin. The percentage of blood-sugar, therefore, appears to bear no direct relation to the state of diabetic coma.

THE SIGNIFICANCE OF COMA.
